Abbreviated regimens for reducing mother-to-child HIV transmission have been studied extensively. Certain regimens have included a postexposure component (antiretroviral medications given to the neonate). Although reduction in maternal viral load during late pregnancy, labor, and delivery seems to be a major factor in the effectiveness of these regimens, an additional effect is believed to occur because the neonate receives prophylaxis, which protects against infection from exposure to maternal HIV during labor and delivery (*13,14*). In a Ugandan perinatal trial, the rate of transmission at 14–16 weeks postpartum was substantially lower for women who received a single dose of nevirapine at the beginning of labor followed by a single dose of nevirapine to the neonate within

72 hours of birth (transmission rate: 13.1%) than for the women who received intrapartum zidovudine followed by 1 week of zidovudine to the neonate (transmission rate: 25.1%) (*15*). Similarly low transmission rates were noted in a study in South Africa in which intrapartum and postpartum antiretroviral medications were used. At 8 weeks postpartum, the transmission rate was 9.3% after intrapartum zidovudine and lamivudine followed by 1 week of zidovudine and lamivudine to mother and neonate, and the transmission rate was 12.3% after a single dose of nevirapine administered to the mother during labor and then to the neonate within 72 hours of birth (*16*). Although these studies lacked control groups, these dosing schedules could not have substantially reduced HIV exposure of the neonate through reducing maternal viral load, demonstrating that a combination of preexposure and postexposure prophylaxis for the neonate reduces HIV transmission. A study in Malawi among women who did not receive intrapartum antiretrovirals compared postnatal prophylaxis with single-dose nevirapine with and without zidovudine for 1 week. The transmission rate at 6–8 weeks was 7.7% among infants who received zidovudine plus nevirapine compared with 12.1% among those who received nevirapine alone (*17*). Although this study did not have a placebo or no-prophylaxis arm, the transmission rate for the zidovudine-nevirapine arm compares favorably with the rate of 21% at 4 weeks, noted in the placebo arm of a study of zidovudine prophylaxis conducted in Cote d'Ivoire (*18*).

Two observational studies with relatively limited numbers documented a potential effect of postnatal zidovudine prophylaxis alone (without intrapartum medication). A review of medical records in New York indicated that zidovudine monotherapy administered to the mother intrapartum or to the infant within 72 hours of birth reduced perinatal transmission >50%; initiating monotherapy for the infant >72 hours after birth was less effective (*19*). Similarly, an analysis of births in the PACTS study demonstrated that zidovudine administered to infants within 24 hours of birth, when mothers had not been treated either antepartum or intrapartum, compared with no treatment for mothers or infants, reduced perinatal transmission by 48% (*20*).

Observational Studies of nPEP

The most direct evidence supporting the efficacy of postexposure prophylaxis is a case-control study of needlestick injuries to health-care workers. In this study, the prompt initiation of zidovudine was associated with an 81% decrease in the risk for acquiring HIV (*21*). Although analogous clinical studies of nPEP have not been conducted, data are available from observational studies and registries.

In a high-risk HIV incidence cohort in Brazil, nPEP instruction and 4-day starter packs of zidovudine and lamivudine were administered to 200 homosexual and bisexual men. Men who began taking nPEP after a self-identified high-risk exposure were evaluated within 96 hours; 92% met the event eligibility criteria (clinician-defined high-risk exposure). Seroincidence was 0.7 per 100 person-years (one seroconversion) among men who took nPEP and 4.1 per 100 person-years among men who did not take nPEP (11 seroconversions) (*22,23*). Subsequent analysis of data from patients who took nPEP and had been followed for a median of 24.2 months indicated 11 seroconversions and a seroincidence of 2.9 per 100 person-years, compared with an expected seroincidence of 3.1 per 100 person years, p>0.97) (*24*). In a study of sexual assault survivors in Sao Paolo, Brazil, women who sought care within 72 hours after exposure were treated for 28 days with either zidovudine and lamivudine (for those without mucosal trauma) or zidovudine, lamivudine, and indinavir (for those with mucosal trauma or those subjected to unprotected anal sex) for 28 days. Women were not treated if they sought care >72 hours after assault, if the assailant was HIV-negative, or if a condom was used and no mucosal trauma was seen. Of 180 women treated, none seroconverted. Of 145 women not treated, four (2.7%) seroconverted (*25*). Although these studies demonstrate that nPEP might reduce the risk for infection after sexual HIV exposures, participants were not randomly assigned, and sample sizes were too small for statistically significant conclusions.

In a study of rape survivors in South Africa, of 480 initially seronegative survivors begun on zidovudine and lamivudine and followed up for at least 6 weeks, one woman seroconverted. She had started taking medications 96 hours after the assault. An additional woman, who sought treatment 12 days after assault, was seronegative at that time but not offered nPEP. At retesting 6 weeks after the assault, she had seroconverted and had a positive polymerase chain reaction result (Personal communication, A. Wulfsohn, MD, Sunninghill Hospital, Gauteng, South Africa).

In a feasibility trial of nPEP conducted in San Francisco, 401 persons with eligible sexual and injection-drug–use exposures were enrolled. No seroconversions were observed among those who completed treatment, those who interrupted treatment, or those who did not receive nPEP (*26*). In a study in British Columbia of 590 persons who completed a course of nPEP, no seroconversions were observed (*27*). In registries from four countries (Australia, France, Switzerland, and the United States), including approximately 2,000 nonoccupational exposure case reports, no confirmed seroconversions

have been attributed to a failure of nPEP in approximately 350 nPEP-treated persons reported to have been exposed to HIV-infected sources. However, the absence of seroconversions might not be attributed to receipt of nPEP but rather to the low per-act risk for infection and incomplete follow-up in the registries.

Case Reports

In addition to these studies, two case reports are of note. In one, a patient who received a transfusion of red blood cells from a person subsequently determined to have early HIV infection began taking combination PEP 1 week after transfusion and continued for 9 months. The patient did not become infected despite the high risk associated with the transfusion of HIV-infected blood (*28*). In the other case, nPEP was initiated 10 days after self-insemination with semen from a homosexual man later determined to have early HIV infection. The woman did not become infected but did become pregnant and gave birth to a healthy infant (*29*).

Although data from the studies and case reports do not provide definitive evidence of the efficacy of nPEP after sexual, injection-drug–use, and other nonoccupational exposures to HIV, the cumulative data demonstrate that antiretroviral therapy initiated soon after exposure and continued for 28 days might reduce the risk for acquiring HIV.

Evidence of Possible Risks from nPEP

Concerns about the potential risks from nPEP as a public health intervention include possible decrease in risk-reduction behaviors resulting from a perception that postexposure treatment is available, the occurrence of serious adverse effects from antiretroviral treatment in otherwise healthy persons, and potential selection for resistant virus (particularly if adherence is poor during the nPEP course). Evidence indicates that these theoretical risks might not be major problems.

Effects on Risk-Reduction Behaviors

The availability or use of nPEP might not lead to increases in risk behavior. Of participants in the nPEP feasibility study in San Francisco, 72% reported a decrease in risk behavior over the next 12 months relative to baseline reported risk behavior, 14% reported no change, and 14% reported an increase (*30*). However, 17% of participants requested a second course of nPEP during the year after the first course, indicating that although participants did not increase risk behaviors, a substantial proportion of the participants did not eliminate risk behaviors. A similar proportion of participants (14%) requested a second course of nPEP at the Fenway Clinic in Boston (*31*). In the Brazil nPEP study of homosexual and bisexual men followed up for a median of 24 months, all groups, including those who elected to take nPEP, reported decreases in risk behavior (*24,32*). Among highly educated (75% with ≥4 years of college), predominantly white (74%) homosexual men who completed a street-outreach interviewer-administered survey in San Francisco, those who reported that they were aware of the availability of nPEP did not report more risk behavior than those who were not aware (*33*). In a study of discordant heterosexual couples, none reported decreased condom use because of the availability of nPEP (*34*).

Antiretroviral Side Effects and Toxicity

Initial concerns about severe side effects and toxicities have been ameliorated by experience with health-care workers who have taken PEP after occupational exposures. Of 492 health-care workers reported to the occupational PEP registry, 63% took at least three medications. Overall, 76% of workers who received PEP and had 6 weeks of follow-up reported certain symptoms (i.e., nausea [57%] and fatigue or malaise [38%]). Only 8% of these workers had laboratory abnormalities, few of which were serious and all of which resolved promptly at the end of antiretroviral treatment (*35*). Six (1.3%) reported severe adverse events, and four stopped taking PEP because of them. Of 68 workers who stopped taking PEP despite exposure to a source person known to be HIV-positive, 29 (43%) stopped because of side effects. According to the U.S. nPEP surveillance registry, among 107 exposures for which nPEP was taken, the regimen initially prescribed was stopped or modified in 22%; modifications or stops were reported because of side effects in half of these instances (*36*). In addition to reports in these registries, serious side effects have been reported (e.g., nephrolithiasis and hepatitis) in the literature.

During 1997–2000, a total of 22 severe adverse events in persons who had taken nevirapine-containing regimens for occupational or nonoccupational postexposure prophylaxis were reported to FDA (*37–38*). Severe hepatotoxicity occurred in 12 (one requiring liver transplantation), severe skin reactions in 14, and both hepatic and cutaneous manifestations occurred in four. Because the majority of occupational exposures do not lead to HIV infection, the risk for using a nevirapine-containing regimen for occupational PEP outweighs the potential benefits. The same rationale indicates that nevirapine should not be used for nPEP.

Selection of Resistant Virus

Antiretroviral PEP does not prevent all infections in occupational and perinatal settings. Similarly, PEP is not expected to have complete efficacy after nonoccupational exposures. In instances where nPEP fails to prevent infection, selection of resistant virus by the antiretroviral drugs is theoretically possible. However, because of the relative paucity of documented nPEP failures for which resistance testing was performed, the likelihood of this occurring is unknown.

PEP failures have been documented after at least one sexual (*39*) and 21 occupational (*38,40*) exposures. Three fourths of these patients were treated with zidovudine monotherapy. Only three received three or more antiretroviral medications for PEP. Among the patients tested, several were infected with strains that were resistant to antiretroviral medications. In a study in Brazil (*24*), virus obtained on day 28 of therapy from the only treated person who seroconverted (whose regimen included 3TC) had a 3TC-resistance mutation. However, the source-person could not be tested. Therefore, whether the mutation was present when the virus was transmitted or whether it developed during nPEP could not be determined.

Selection of resistant virus might occasionally result from the use of nPEP. However, because the majority of nonoccupational exposures do not lead to HIV infection and because the use of combination antiretroviral therapy might reduce further the transmission rate, such occurrences are probably rare. For patients who seroconvert despite nPEP, resistance testing should be considered to guide early and subsequent treatment decisions.

Cost-Effectiveness of nPEP

Although the potential benefits of nPEP to persons are measured by balancing its anticipated efficacy after a given exposure against individual health risks, the value of nPEP as a public health intervention is best addressed at the population level by using techniques such as cost-benefit analysis. Such analyses have been published. One cost-effectiveness evaluation of nPEP in different potential exposure scenarios in the United States reported it to be cost-effective only in situations in which the sex partner source was known to be HIV-infected or after unprotected receptive anal intercourse with a homosexual or bisexual man of unknown serostatus (*41,42*). A similar analysis in France reported that nPEP was cost-saving for unprotected receptive anal intercourse with a partner known to be HIV-infected and cost-effective for receptive anal intercourse with a homosexual or bisexual partner of unknown serostatus. It was not cost-effective for penile-vaginal sex, insertive anal intercourse, or other exposures considered (*43*).

Another study and anecdotal reports indicate difficulty limiting nPEP to the exposures most likely to benefit from it. In British Columbia, where guidelines for nPEP use have been implemented (*5*), an analysis indicated that >50% of those receiving nPEP should not, according to the guidelines, have been treated (e.g., for exposure to intact skin). The use of nPEP in these circumstances doubled the estimated cost per HIV infection prevented ($530,000 versus $230,000) (*44*).

Even if nPEP is cost-effective for the highest risk exposures, behavioral interventions are more cost-effective (*41,45*). This emphasizes the importance, when considering nPEP, of providing risk-avoidance and risk-reduction counseling to reduce the occurrence of future HIV exposures.

Evidence of Current Practice

Although 40,000 new HIV infections occur in the United States each year, relatively few exposed persons seek care after nonoccupational exposure. Certain exposures are unrecognized. Certain patients have frequently recurring exposures and would not benefit from nPEP because 4 weeks of potential protection cannot substantially reduce their overall risk for acquiring HIV infection. In addition, certain clinicians and exposed patients are unaware of the availability of nPEP or unconvinced of its efficacy and safety. Finally, access to knowledgeable clinicians or a means of paying for nPEP might constrain its use.

Certain populations in the United States remain at high risk for exposure. In a cohort study of homosexual and bisexual men, 17% reported at least one condom failure during the 6 months preceding study enrollment (*46*). Other studies indicate that increasing use of highly active antiretroviral therapy (HAART) by HIV-infected persons might be leading some persons to have unprotected sex more frequently, in part because of the belief that lowered viral load substantially reduces infectivity (*47–50*). This finding is supported by increased rates of sexually transmitted infections among HIV-infected patients (*51*). In a California study, 69% of discordant heterosexual couples reported having had unprotected sex during the preceding 6 months (*34*).

Since 1998, certain clinicians have recommended wider availability and use of nPEP (*52–58*), and others have been more cautious about implementing it in the absence of definitive evidence of efficacy (*59,60*). Multiple public health jurisdictions, including the New York State AIDS Institute, the San Francisco County Health Department, the Massachusetts Department of Public Health, the Rhode Island

Department of Health, and the California State Office of AIDS, have issued policies or advisories for nPEP use. Some of these recommendations have focused on sexual assault survivors, who constitute few of the estimated 40,000 new HIV infections annually in the United States.

Surveys of clinicians and facilities indicate a need for more widespread implementation of guidelines and protocols for nPEP use (*61*). In a survey of Massachusetts emergency department directors, 52% of facilities had received nPEP requests during the preceding year, but only 15% had written nPEP protocols (*62*). Similarly, in a survey of Massachusetts clinicians, approximately 20% had a written nPEP protocol (*63*). Among pediatric emergency medicine specialists surveyed throughout the United States and Canada, approximately 20% had a written policy about nPEP use, but 33% had prescribed it for children and adolescents; different prescribing practices were reported (*64*). In a survey of 27 European Union countries, 23 had guidelines for occupational PEP use, but only six had guidelines for nPEP use (*65*).

Evidence indicates considerable awareness of nPEP and interest in its use among potential patients. In a cohort study of homosexual and bisexual men, 60% were willing to participate in a study of nPEP if it involved a single daily dose of medication; 30% were willing to take 3 doses daily (*66*). Among men surveyed at a "gay pride" festival in Atlanta, although only 3% had used nPEP, 26% planned to if exposed in the future (*67*). When nPEP studies were established in San Francisco, approximately 400 persons sought treatment in 2½ years (*24*). At a clinic primarily serving homosexual and bisexual men in Boston, 71 requests for nPEP were evaluated in 1½ years (*30*). In a California study of heterosexual discordant couples, 28% had heard of nPEP, 55% of seronegative partners believed that it was effective, and 78% reported they would take it if exposed (*34*).

No nationally representative data exists on nPEP use in the United States. In 1998, CDC established a national nPEP surveillance registry that accepts voluntary reports by clinicians. Although approximately 800 reports have been received, the majority of clinicians prescribing nPEP do not report to the registry. Similarly, low reporting rates were obtained in attempts to establish voluntary registries to monitor occupational PEP and antiretroviral use during pregnancy. No national surveys of clinicians have been reported. However, one multisite HIV vaccine trial largely conducted in the United States has assessed nPEP use by 5,418 participants, who included men who have sex with men (94%) and heterosexual women at high risk (6%). Two percent of trial participants from 27 study sites reported having taken nPEP during the trial. Supplementary data from six U.S. sites indicated that 46% of participants had heard of nPEP. Enrollment at one of seven California sites (odds ratio [OR] = 3.2), having a known positive partner (OR = 2.0), higher educational level (OR = 1.4), and greater recreational drug use (OR = 1.2) were significant predictors of having used nPEP ($p<0.05$) (*68*).

Evaluation of Persons Seeking Care After Potential Nonoccupational Exposure to HIV

The effective delivery of nPEP after exposures that have a substantial risk for HIV infection requires prompt evaluation of patients and consideration of biomedical and behavioral interventions to address current and ongoing health risks. This evaluation should include determination of the HIV status of the potentially exposed person, the timing and characteristics of the most recent exposure, the frequency of exposures to HIV, the HIV status of the source, and the likelihood of concomitant infection with other pathogens or negative health consequences of the exposure event.

HIV Status of the Potentially Exposed Person

Because persons who are infected with HIV might not be aware they are infected, baseline HIV testing should be performed on all persons seeking evaluation for potential nonoccupational HIV exposure. If possible, this should be done with an FDA-approved rapid test kit (with results available within an hour). If rapid tests are not available, an initial treatment decision should be made based on the assumption that the potentially exposed patient is not infected, pending HIV test results.

Timing and Frequency of Exposure

Available data indicate that nPEP is less likely to be effective if initiated >72 hours after HIV exposure. If initiation of nPEP is delayed, the likelihood of benefit might not outweigh the risks inherent in taking antiretroviral medications.

Because nPEP is not 100% effective in preventing transmission and because antiretroviral medications carry a certain risk for adverse effects and serious toxicities, nPEP should be used only for infrequent exposures. Persons who engage in behaviors that result in frequent, recurrent exposures that would require sequential or near-continuous courses of antiretroviral medications (e.g., discordant sex partners who rarely use condoms or injection-drug users who often share injection equipment) should not take nPEP. In these instances, exposed persons should instead be provided with intensive risk-reduction interventions.

HIV Status of Source

Patients who have had sexual, injection-drug–use, or other nonoccupational exposures to potentially infectious fluids of persons known to be HIV infected are at risk for acquiring HIV infection and should be considered for nPEP if they seek treatment within 72 hours of exposure. If possible, source persons should be interviewed to determine his or her history of antiretroviral use and most recent viral load because this information might provide information for the choice of nPEP medications.

Persons with exposures to potentially infectious fluids of persons of unknown HIV status might or might not be at risk for acquiring HIV infection. When the source is known to be from a group with a high prevalence of HIV infection (e.g., a homosexual or bisexual man, an injection–drug user, or a commercial sex worker), the risk for transmission might be increased. The risk for transmission might be especially great if the source person has been infected recently, when viral burden in blood and semen might be particularly high (*69,70*). However, ascertaining this in the short time available for nPEP evaluation is rarely possible. When the HIV status of the source is unknown, it should be determined whether the source is available for HIV testing. If the risk associated with the exposure is considered substantial, nPEP can be started pending determination of the HIV status of the source and then stopped if the source is determined to be noninfected.

Transmission Risk from the Exposure

Although the estimated per-act transmission risk from unprotected exposure to a partner known to be HIV infected is relatively low for different types of exposure (Table 1), different nonoccupational exposures are associated with different levels of risk (*71–79*). The highest levels of estimated per-act risk for HIV transmission are associated with blood transfusion, needle sharing by injection-drug users, receptive anal intercourse, and percutaneous needlestick injuries. Insertive anal intercourse, penile-vaginal exposures, and oral sex represent substantially less per-act risk.

TABLE 1. Estimated per-act risk for acquisition of HIV, by exposure route*

Exposure route	Risk per 10,000 exposures to an infected source	Reference
Blood transfusion	9,000	74
Needle-sharing injection-drug use	67	75
Receptive anal intercourse	50	76, 77
Percutaneous needle stick	30	78
Receptive penile-vaginal intercourse	10	76, 77, 79
Insertive anal intercourse	6.5	76, 77
Insertive penile-vaginal intercourse	5	76, 77
Receptive oral intercourse	1	77†
Insertive oral intercourse	0.5	77†

* Estimates of risk for transmission from sexual exposures assume no condom use.
† Source refers to oral intercourse performed on a man.

A history should be taken of the specific sexual, injection-drug–use, or other behaviors that might have led to, or modified, a risk for acquiring HIV infection. Eliciting a complete description of the exposure and information about the HIV status of the partner(s) can substantially lower (e.g., if the patient was the insertive partner or a condom was used) or increase (e.g., if the partner is known to be HIV-positive) the estimate of risk for HIV transmission resulting from a specific exposure.

In addition to sexual and injection-drug–use exposures, percutaneous injuries from needles discarded in public settings (e.g., parks and buses) result in requests for nPEP with a certain frequency. Although no HIV infections from such injuries have been documented, concern exists that syringes discarded by injection-drug users (e.g., for whom the HIV infection rate is higher than that for diabetics) might pose a substantial risk. However, these injuries typically involve small-bore needles that contain only limited amounts of blood, and the viability of any virus present is limited. In a study of syringes used to administer medications to HIV-infected persons, only 3.8% had detectable HIV RNA (*72*). In a study of the viability of virus in needles, viable virus was recovered from 8% at 21 days when the needles had been stored at room temperature; <1% had viable virus after 1 week of storage at higher temperatures (*73*).

Bite injuries represent another potential means of transmitting HIV. However, HIV transmission by this route has been reported rarely (*80-82*). Transmission might theoretically occur either though biting or receiving a bite from an HIV-infected person. Biting an HIV-infected person, resulting in a break in the skin, exposes the oral mucous membranes to infected blood; being bitten by an HIV-infected person exposes nonintact skin to saliva. Saliva that is contaminated with infected blood poses a substantial exposure risk. Saliva that is not contaminated with blood contains HIV in much lower titers and constitutes a negligible exposure risk (*83*).

Evaluation for Sexually Transmitted Infections, Hepatitis, and Emergency Contraception

Evaluation for sexually transmitted infections is important because these infections might increase the risk for acquiring HIV infection from a sexual exposure. In 1996, an estimated 5,042 new HIV infections were attributable to sexually transmitted infection at the time of HIV exposure (*84*). In addi-

tion, any sexual exposure that presents a risk for HIV infection might also place a patient at risk for acquiring other sexually transmitted infections, including hepatitis B. Prophylaxis for sexually transmitted disease, testing for hepatitis, and vaccination for hepatitis B (for those not immune) should be considered (*85*).

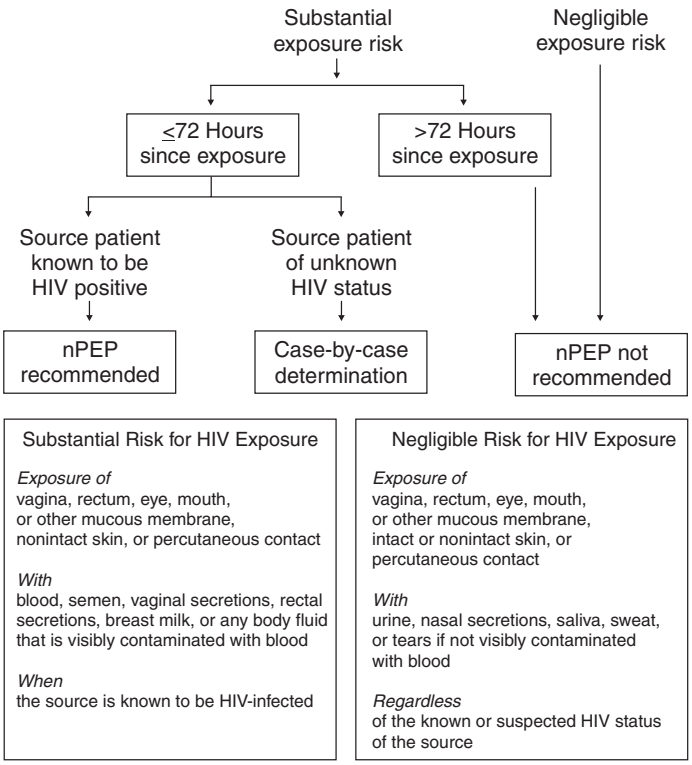
For women of reproductive capacity who have had genital exposure to semen, the risk for pregnancy also exists. In these instances, emergency contraception should be discussed with the potentially exposed patient.

Recommendations for Use of Antiretroviral nPEP

A 28-day course of HAART is recommended for persons who have had nonoccupational exposure to blood, genital secretions, or other potentially infected body fluids of a persons known to be HIV infected when that exposure represents a substantial risk for HIV transmission (Figure 1) and when the person seeks care within 72 hours of exposure. When indicated, antiretroviral nPEP should be initiated promptly for the best chance of success.

Evidence from animal studies and human observational studies demonstrate that nPEP administered within 48–72 hours and continued for 28 days might reduce the risk for acquiring HIV infection after mucosal and other nonoccupational exposures. The sooner nPEP is administered after exposure, the more likely it is to interrupt transmission. Because HIV is an incurable transmissible infection that affects the quality and duration of life, HAART should be used to maximally suppress local viral replication that otherwise might occur in the days after exposure and potentially lead to a disseminated, established infection (*11,86*). One of the HAART combinations recommended for the treatment of persons with established HIV infection should be selected on the basis of adherence, toxicity, and cost considerations (Tables 2 and 3) (*87,88*).

FIGURE 1. Algorithm for evaluation and treatment of possible nonoccupational HIV exposures



No evidence indicates that any specific antiretroviral medication or combination of medications is optimal for use as nPEP. However, on the basis of the degree of experience with individual agents in the treatment of HIV-infected persons, certain agents and combinations are preferred. Preferred regimens include efavirenz and lamivudine or emtricitabine with zidovudine or tenofovir (as a nonnucleoside-based regimen) and lopinavir/ritonavir (coformulated in one tablet as Kaletra®) and zidovudine with either lamivudine or emtricitabine. Different alternative regimens are possible (Table 2).

No evidence indicates that a three-drug HAART regimen is more likely to be effective than a two-drug regimen. The recommendation for a three-drug HAART regimen is based on the assumption that the maximal suppression of viral replication afforded by HAART (the goal in treating HIV-infected persons) will provide the best chance of preventing infection in a person who has been exposed. Clinicians and patients who are concerned about potential adherence and toxicity issues associated with a three-drug HAART regimen might consider the use of a two-drug regimen (i.e., a combination of two reverse transcriptase inhibitors). Regardless of the regimen chosen, the exposed person should be counseled about the potential associated side effects and adverse events that require immediate medical attention. The use of medications to treat symptoms (e.g., antiemetics or antimotility agents) might improve adherence in certain instances.

Although certain preliminary studies have evaluated the penetration of antiretroviral medications into genital tract secretions and tissues (*89,90*), evidence is insufficient to recommend a specific antiretroviral medication as most effective for nPEP. In addition, new antiretroviral medications might become available. As new medications and new information become available, these recommendations will be amended and updated.

When the source-person is available for interview, his or her history of antiretroviral medication use and most recent

TABLE 2. Antiretroviral regimens for nonoccupational postexposure prophylaxis of HIV infection

Preferred regimens	
NNRTI*-based	Efavirenz† plus (lamivudine or emtricitabine) plus (zidovudine or tenofovir)
Protease inhibitor (PI)-based	Lopinavir/ritonavir (co-formulated as Kaletra) plus (lamivudine or emtricitabine) plus zidovudine
Alternative regimens	
NNRTI-based	Efavirenz plus (lamivudine or emtricitabine) plus abacavrir or didanosine or stavudine§
PI-based	Atazanavir plus (lamivudine or emtricitabine) plus (zidovudine or stavudine or abacavir or didanosine) or (tenofovir plus ritonavir [100 mg/day])
	Fosamprenavir plus (lamivudine or emtricitabine) plus (zidovudine or stavudine) or (abacavir or tenofovir or didanosine)
	Fosamprenavir/ritonavir¶ plus (lamivudine or emtricitabine) plus (zidovudine or stavudine or abacavir or tenofovir or didanosine)
	Indinavir/ritonavir¶** plus (lamivudine or emtricitabine) plus (zidovudine or stavudine or abacavir or tenofovir or didanosine)
	Lopinavir/ritonavir (co-formulated as Kaletra) plus (lamivudine or emtricitabine) plus (stavudine or abacavir or tenofovir or idanosine)
	Nelfinavir plus (lamivudine or emtricitabine) plus (zidovudine or stavudine or abacavir or tenofovir or didanosine)
	Saquinavir (hgc* or sgc*)/ritonavir† plus (lamivudine or emtricitabine) plus (zidovudine or stavudine or abacavir or tenofovir or didanosine)
Triple NRTI*	Abacavir plus lamivudine plus zidovudine (only when an NONRTI- or PI-based regimen cannot or should not be used)

* NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; sgc = soft-gel saquinavir capsule (Fortovase); hgc = hard-gel saquinavir capsule (Invirase).
† Efavirenz should be avoided in pregnant women and women of childbearing potential.
§ Higher incidence of lipoatrophy, hyoerlipidemia, and mitochondrial toxicities associated with stavudine than with other NRTIs.
¶ Low-dose (100–400 mg) ritonavir. See Table 4 for doses used with specific PIs.
** Use of ritonavir with indinavir might increase risk for renal adverse events.

viral load measurement should be considered when selecting antiretroviral medications for nPEP. This information might help avoid prescribing antiretroviral medications to which the source-virus is likely to be resistant. If the source-person is willing, the clinician might consider drawing blood for viral load and resistance testing, the results of which might be useful in modifying the initial nPEP medications if the results can be obtained promptly (*91*).

For persons who have had nonoccupational exposure to potentially infected body fluids of a person of unknown HIV infection status, when that exposure represents a substantial risk for HIV transmission (Figure 1) and when care is sought within 72 hours of exposure, no recommendations are made either for or against the use of antiretroviral nPEP. Clinicians should evaluate the risk for and benefits of this intervention on a case-by-case basis.

When a source-person is not known to be infected with HIV, the risk for exposure (and therefore the potential benefit of nPEP) is unknown. Prescribing antiretroviral medication in these cases might subject patients to risks that are not balanced with the potential benefit of preventing the acquisition of HIV infection. Judging whether the balance is appropriate depends entirely on the circumstances of the possible exposure (i.e., the risk that the source is HIV infected and the risk for transmission if the source is HIV infected) and is best determined through discussion between the clinician and the patient.

If the source-person is available for interview, additional information about risk history can be obtained and permission for an HIV test requested to assist in determining the likelihood of HIV exposure. When available, FDA-approved rapid HIV tests are preferable for obtaining this information as quickly as possible. These additional factors might assist in the decision whether to start or complete a course of nPEP. If data to clearly determine risk are not immediately available, clinicians might consider initiating nPEP while further assessments are being made and then stopping it when other information is available (e.g., the source-person is determined to be noninfected).

For persons whose exposure histories represent no substantial risk for HIV transmission (Figure 1) or who seek care >72 hours after potential nonoccupational HIV exposure, the use of antiretroviral nPEP is not recommended. When the risk for HIV transmission is negligible, limited benefit is anticipated from the use of nPEP. In addition, animal and human study data demonstrate that nPEP is less likely to prevent HIV transmission when initiated >72 hours after exposure. Because the risks associated with antiretroviral medications are likely to outweigh the potential benefit of nPEP in these circumstances, nPEP is not recommended for such exposures, regardless of the HIV status of the source. However, it cannot be concluded on the basis of the available data that nPEP will be completely ineffective when initiated >72 hours after exposure. Moreover, data do not indicate an absolute time after exposure beyond which nPEP will not be effective. When

TABLE 3. Highly active antiretroviral therapy medications, adult dosage, cost, and side effects

Medication	Adult dosage*	Cost (in dollars) for 4 weeks†	Side effects and toxicities
Combination tablets			
Lopinavir/ritonavir (Kaletra®) §	3 tablets twice daily 400 mg lopinavir/100 mg ritonavir	650	Diarrhea, nausea, vomiting; asthenia; elevated transaminases; hyperglycemia; fat redistribution; lipid abnormalities; possible increased bleeding in persons with hemophilia; and pancreatitis
Zidovudine/lamivudine (Combivir®)	1 tablet twice daily 300 mg zidovudine/150 mg lamivudine	640	See following individual medications
Zidovudine/lamivudine/abacavir (Trizivir®)	1 tablet twice daily 300 mg zidovudine/150 mg lamivudine/ 300 mg abacavir	1,020	See following individual medications
Lamivudine/abacavir (Epzicom®)	1 tablet once daily 300 mg lamivudine/600 mg abacavir	760	See following individual medications
Emtricitabine/tenofovir (Truvada®)	1 tablet once daily 200 mg emtricitabine/300 mg tenofovir	800	See following individual medications
Single agents			
Nucleoside and nucleotide reverse transcriptase inhibitors (Side effects as a class: lactic acidosis, severe hepatomegaly with steatosis, including some fatal cases)			
Abacavir (Ziagen®, ABC)§	300 mg twice daily or 600 mg once daily	400	Severe hypersensitivity reaction (can be fatal); nausea; and vomiting
Didanosine (Videx®, ddI)§	>60 kg (132 lb) body weight: 200 mg twice daily or 400 mg daily; if with tenofovir, 250 mg/daily	260	Pancreatitis; nausea, diarrhea; and peripheral neuropathy
	<60 kg (132 lb): 125 mg twice daily or 250 mg daily; if with tenofovir, dose not established		
	Do not use with stavudine (d4T, Zerit) during pregnancy; avoid ddI/d4T combination in general because of increased risk for adverse events (e.g., neuropathy, pancreatitis, and hyperlactatemia)		
Emtricitabine (Emtriva®, FTC)	200 mg once daily	280	Minimal toxicity; lactic acidosis and hepatic steatosis a rare but possibly life-threatening event
Lamivudine (Epivir®, 3TC)§	150 mg twice daily or 300 mg once daily	300	Minimal toxicity; lactic acidosis and hepatic steatosis a rare but possibly life-threatening event
Stavudine (Zerit®, d4T)§	>60 kg (132 lb) body weight: 40 mg twice daily	320	Pancreatitis; peripheral neuropathy; rapidly progressive ascending neuromuscular weakness (rare)
	<60 kg (132 lb) body weight: 30 mg twice daily		
	Do not use with didanosine (ddI, Videx) during pregnancy; avoid ddI/d4T combination in general because of increased risk for adverse events (e.g., neuropathy, pancreatitis, and hyperlactatemia)		
Tenofovir (Viread®)	300 mg daily	400	Nausea, vomiting, diarrhea; headache; asthenia; flatulence; and renal impairment
Zidovudine (Retrovir®, AZT)§	200 mg three times daily or 300 mg twice daily	350	Bone marrow suppression (anemia, neutropenia); gastrointestinal intolerance; headache; insomnia; asthenia; and myopathy

TABLE 3. (*Continued*) Highly active antiretroviral therapy medications, adult dosage, cost, and side effects

Medication	Adult dosage*	Cost (in dollars) for 4 weeks†	Side effects and toxicities
Single agents			
Non-nucleoside reverse transcriptase inhibitors (Side effects as a class: Stevens-Johnson syndrome)			
Efavirenz (Sustiva®)	600 mg daily at bedtime Do not use during known or possible pregnancy	420	Rash; central nervous system symptoms (e.g., dizziness, impaired concentration, insomnia, and abnormal dreams); transaminase elevation; and false-positive cannabinoid test
Protease inhibitors (Side effects as a class: gastrointestinal intolerance, hyperlipidemia, hyperglycemia, diabetes, fat redistribution, and possible increased bleeding in hemophiliacs)			
Atazanavir (Reyataz®)	400 mg once daily; if administered with tenofovir plus ritonavir, 300 mg once daily	760	Indirect hyperbilirubinemia; prolonged PR interval (use caution in patients with underlying cardiac conduction defects or on concomitant medications that can cause PR prolongation)
Fosamprenavir (Lexiva®)§	1,400 mg twice daily	1,260	Gastrointestinal intolerance, nausea, vomiting, diarrhea; rash; elevated transaminases; and headache
Indinavir (Crixivan®)	800 mg every 8 hours With ritonavir (might increase risk for renal adverse events): 800 mg indinavir and 100 mg ritonavir every 12 hours or 800 mg indinavir and 200 mg ritonavir every 12 hours	500	Gastrointestinal intolerance, nausea; nephrolithiasis; headache; asthenia; blurred vision; metallic taste; thrombocytopenia; hemolytic anemia; and indirect hyperbilirubinemia (inconsequential)
Nelfinavir (Viracept®)§	750 mg three times daily or 1,250 mg twice daily	600	Diarrhea; and elevated transaminases
Ritonavir (Norvir®)§	See doses used in combination with other specific protease inhibitors	700–2,800	Gastrointestinal intolerance; nausea, vomiting, diarrhea; paresthesias; hepatitis; panreatitis; asthenia; and taste perversion; many drug interactions
Saquinavir (hard-gel capsule) (Invirase®)	With ritonavir: 400 mg saquinavir and 400 mg ritonavir twice daily or 1,000 mg saquinavir and 100 mg ritonavir twice daily	270	Gastrointestinal intolerance; nausea, diarrhea; headache; and elevated transaminases
Saquinavir (soft-gel capsule) (Fortavase®)	With Ritonavir: 400 mg saquinavir and 400 mg ritonavir twice daily or 1,000 mg saquinavir and 100 mg ritonavir twice daily	460	Gastrointestinal intolerance; nausea, diarrhea; abdominal pain; dyspepsia; headache; and elevated transaminases

Available at http://www.aidsinfo.nih.gov/guidelines/default_db2.asp?id=50 (refer to website for updated versions). Bartlett JG, Finkbeiner AK. HIV drugs: the guide to living with HIV infection. 2001. 11-13-2001. Available at http://www.thebody.com/jh/bartlett/drugs.html.

safer and more tolerable drugs are used, the risk-benefit ratio of providing nPEP >72 hours postexposure is more favorable. Therefore, clinicians might consider prescribing nPEP after exposures that confer a serious risk for transmission, even if the exposed person seeks care >72 hours postexposure if, in the clinician's judgment, the diminished potential benefit of nPEP outweighs the potential risk for adverse events from antiretroviral drugs.

Considerations for All Patients Treated with Antiretroviral nPEP

Use of Starter Packs

Patients might be under considerable emotional stress when seeking care after a potential HIV exposure and might not attend to, or retain, all the information relevant to making a decision about nPEP. Clinicians should give an initial prescription for 3–5 days of medication and schedule a follow-up visit to review the results of baseline HIV testing (if rapid tests are not used), provide additional counseling and support, assess medication side effects and adherence, and provide additional medication if appropriate (with an altered regimen if indicated by side effects or laboratory test results).

Scientific Consultation

When clinicians are not experienced with using HAART or when information from source-persons indicates the possibility of antiretroviral resistance, consultation with infectious disease or other HIV-care specialists, if it is available immediately, might be warranted before prescribing nPEP. Similarly, when considering prescribing nPEP to pregnant women or children, consultation with obstetricians or pediatricians might be advisable. However, if such consultation is not immediately available, initiation of nPEP should not be delayed. An initial nPEP regimen should be started and, if necessary, revised after consultation is obtained. Patients who seek nPEP might benefit from referral for psychological counseling that helps ease the anxiety about possible HIV exposure, strengthens risk-reduction behaviors, and promotes adherence to nPEP regimens if prescribed.

Facilitating Adherence

Adherence to antiretroviral medications can be challenging, even for 28 days. In addition to common side effects such as nausea and fatigue, each dose reminds the patient of his or her risk for acquiring HIV infection. Adherence has been reported to be especially poor among sexual assault survivors (*92–96*). Steps to maximize medication adherence include prescribing medications with fewer doses and fewer pills per dose, educating patients about the importance of adherence and about potential side effects, offering ancillary medications for side effects (e.g., anti-emetics) if they occur, and providing access to ongoing encouragement and consultation by phone or office visit.

Follow-up Testing and Care

All patients seeking care after HIV exposure should be tested for the presence of HIV antibodies at baseline and at 4–6 weeks, 3 months, and 6 months after exposure to determine whether HIV infection has occurred. In addition, testing for sexually transmitted diseases, hepatitis B and C, and pregnancy should be offered (Table 4).

Patients should be instructed about the signs and symptoms associated with acute retroviral infection (Table 5), especially fever and rash (*97*), and asked to return for evaluation if these occur during or after nPEP. Acute HIV infection is associated with high viral loads. However, clinicians should be aware that available assays might yield low viral-load results (e.g., <3,000) in noninfected persons. Such false-positive results can lead to misdiagnosis of HIV infection (*98*).

Transient, low-grade viremia has been observed both in macaques exposed to SIV (*99*) and humans exposed to HIV who were administered antiretroviral PEP (*100*) and did not become infected. In certain cases, this outcome might represent aborted infection rather than false-positive test results, but this can be determined only through further study. For patients with clinical or laboratory evidence of acute HIV infection, continuing antiretroviral therapy for >28 days might be prudent because such early treatment (no longer prophylaxis) might slow the progression of HIV disease (*101*). Patients with acute HIV infection should be transferred to the care of HIV treatment specialists.

In addition, clinicians who provide nPEP should monitor liver function, renal function, and hematologic parameters as indicated by the prescribing information found in antiretroviral treatment guidelines (*87,102,103*), package inserts, and the *Physician's Desk Reference* (Table 3). Unusual or severe toxicities from antiretroviral drugs should be reported to the manufacturer or FDA.

HIV Prevention Counseling

The majority of persons who seek care after a possible HIV exposure do so because of failure to initiate or maintain effective risk-reduction behaviors. Notable exceptions are sexual assault survivors and children with community-acquired needlestick injuries.

TABLE 4. Recommended laboratory evaluation for nonoccupational postexposure prophylaxis (nPEP) of HIV infection

Test	Baseline	During nPEP*	4–6 Weeks after exposure	3 Months after exposure	6 Months after exposure
HIV antibody testing	E†, S§		E	E	E
Complete blood count with differential	E	E			
Serum liver enzymes	E	E			
Blood urea nitrogen/creatinine	E	E			
Sexually transmitted diseases screen (gonorrhea, chlamydia, syphilis)	E, S	E¶	E¶		
Hepatitis B serology	E, S		E¶	E¶	
Hepatitis C serology	E, S			E	E
Pregnancy test (for women of reproductive age)	E	E¶	E¶		
HIV viral load	S		E**	E**	E**
HIV resistance testing	S		E**	E**	E**
$CD4^+$T lymphocyte count	S		E**	E**	E**

* Other specific tests might be indicated dependent on the antiretrovirals prescribed. Literature pertaining to individual agents should be consulted.
† E = exposed patient, S = source.
§ HIV antibody testing of the source patient is indicated for sources of unknown serostatus.
¶ Additional testing for pregnancy, sexually transmitted diseases, and hepatitis B should be performed as clinically indicated.
** If determined to be HIV infected on follow-up testing; perform as clinically indicated once diagnosed.

TABLE 5. Expected frequency of associated signs and symptoms among persons with signs and symptoms of acute retroviral syndrome

Symptom/sign	%
Fever	96
Lymphadenopathy	74
Pharyngitis	70
Rash Erythematous maculopapular with lesions on face, trunk and sometimes extremities, including palms and soles; mucocutaneous ulceration involving mouth, esophagus or genitals	70
Myalgia or arthralgia	54
Diarrhea	32
Headache	32
Nausea and vomiting	27
Hepatosplenomegaly	14
Weight loss	13
Thrush	12
Neurologic symptoms Meningoencephalitis or aseptic meningitis; peripheral neuropathy or radiculopathy; facial palsy; Guillain-Barré syndrome; brachial neuritis; or cognitive impairment or psychosis	12

Although nPEP might reduce the risk for HIV infection, it is not believed to be 100% effective. Therefore, patients should practice protective behaviors with sex partners (e.g., abstinence or consistent use of male condoms) or drug-use partners (e.g., avoidance of shared injection equipment) throughout the course of nPEP to avoid transmission to others if they become infected, and after nPEP to avoid future HIV exposures.

At follow-up visits, clinicians should assess their patients' needs for behavioral intervention, education, and services. This assessment should include frank, nonjudgmental questions about sexual behaviors, alcohol use, and illicit drug use. Clinicians should help patients identify ongoing risk issues and develop plans for improving their use of protective behaviors (*104*).

To help patients obtain indicated interventions and services, clinicians should be aware of local resources for high-quality HIV education and ongoing behavioral risk reduction, counseling and support, inpatient and outpatient alcohol and drug-treatment services, substance/drug abuse treatment programs, family and mental health counseling services, and support programs for HIV-infected persons. Information about publicly funded HIV prevention programs can be obtained from state or local health departments.

Management of Source Persons

When source-persons are seen during the course of evaluating a patient for potential HIV exposure, clinicians should also assess the source-person's access to relevant medical care, behavioral intervention, and social support services. If needed care cannot be provided directly, clinicians should help source-persons obtain care in the community.

If a new diagnosis of HIV infection is made or evidence of other sexually transmitted infection is identified, the patient

should be assisted in notifying their sexual and drug-use contacts. Assistance with confidential partner notification (without revealing the patient's identity) is available through local health departments.

Reporting and Confidentiality

Because of the emotional, social, and potential financial consequences of possible HIV infection, clinicians should handle nPEP evaluations with the highest level of confidentiality. Confidential reporting of sexually transmitted infections and newly diagnosed HIV infections to health departments should take place as dictated by local law and regulations.

For cases of sexual assault, clinicians should document their findings and assist patients with notifying local authorities. HIV test results should be recorded separately from the findings of the sexual assault examination to protect patients' confidentiality in the event that medical records are later released for legal proceedings. Certain states and localities have special programs to provide reimbursement for medical therapy, including antiretroviral medication after sexual assault, and these areas might have specific reporting requirements. When the sexual abuse of a child is suspected or documented, the clinician should report it in compliance with state and local law and regulations.

Considerations for Vulnerable Populations

Pregnant Women and Women of Childbearing Potential

Considerable experience has been gained in recent years in the safe and appropriate use of antiretroviral medications during pregnancy, either for the benefit of the HIV-infected woman's health or to prevent transmission to newborns. To facilitate the selection of antiretroviral medications likely to be both effective and safe for the developing fetus, clinicians should consult DHHS guidelines (*102*) before prescribing nPEP for a woman who is or might be pregnant.

Because of potential teratogenicity, efavirenz should not be used in any nPEP regimen during pregnancy or among women of childbearing age at risk for becoming pregnant during the course of antiretroviral prophylaxis (Table 3). A protease inhibitor- or nucleoside reverse transcriptase inhibitor-based regimen should be considered in these circumstances. When efavirenz is prescribed to women of childbearing potential, they should be instructed about the need to avoid pregnancy. Because the effect of efavirenz on hormonal contraception is unknown, women using such contraception should be informed of the need to use an additional method (e.g., barrier contraception). In addition, because of reports of maternal and fetal mortality attributed to lactic acidosis associated with prolonged use of d4T in combination with ddI in HIV-infected pregnant women, this combination is not recommended for use in an nPEP regimen (*105*).

Children

Potential HIV exposures in children occur most often by accident (e.g., needlesticks in the community, fights, or playground incidents resulting in bleeding by an HIV-infected child) or by sexual abuse or assaults (*106*). In a review of charts from 1 year in the pediatric emergency department of one hospital, 10 children considered for nPEP were identified (six because of sexual assault and four because of needlestick injury). Eight began taking nPEP, but only two completed the 4-week course (*63,107*). An analysis of 9,136 reported acquired immunodeficiency syndrome cases in children identified 26 who were sexually abused with confirmed or suspected exposure to HIV infection (*108*).

The American Academy of Pediatrics has issued nPEP guidelines for pediatric patients (*109*). In addition, DHHS pediatric antiretroviral treatment guidelines (*103*) provide information about the use of antiretroviral agents in children. For young children who cannot swallow capsules or tablets and to ensure appropriate dosing for drugs that do not have capsule/tablet formulations that allow pediatric dosing, drugs for which pediatric formulations are available might need to be prescribed (Table 3). Adherence to the prescribed medications will depend on the involvement of, and support provided to, parents or guardians.

Sexual Assault Survivors

Use of nPEP for sexual assault survivors has been widely encouraged both in the United States and elsewhere (*56, 94,110,111*). Sexual assault is relatively common among women: 13% of a national sample of adult women reported having ever been raped (60% before age 18), and 5% reported having been raped more than once (*112*). Sexual assault is not uncommon among men. In one series from an emergency department, 5% of reported rapes involved men sexually assaulted by men (*113*). Males accounted for 11.6 % of rapes reported among persons aged ≥12 years who responded to the National Crime Victimization Survey in 1999 (*114*). However, only three documented cases of HIV infection resulting from sexual assault have been published (*94,115,116*). In observational studies, HIV infections have been temporally associated with sexual assault (Personal communication,

A. Wulfsohn, MD, Sunninghill Hospital, Gauteng, South Africa).

Studies have examined HIV infection rates for sexual assailants (*117,118*). The largest of these, an evaluation of men incarcerated in Rhode Island, determined that 1% of those convicted of sexual assault were HIV infected when they entered prison, compared with 3% of all prisoners and 0.3% of the general male population (*119*).

Sexual assault typically has multiple characteristics that increase the risk for HIV transmission if the assailant is infected. In one prospective study of 1,076 sexual assault cases, 20% were attacked by multiple assailants, 39% were assaulted by strangers, 83% of females were vaginally penetrated, and 17% overall were sodomized. Genital trauma was documented in 53% of those assaulted, and sperm or semen was detected in 48% (*120*). In another study, in which toluidine blue dye was used as an adjunct to naked-eye examination, 40% of assaulted women (70% of nulliparas) had detectable vaginal lacerations, compared with 5% of women examined after consensual sex (*121*).

Despite these risks and the establishment of multidisciplinary support services, sexual assault survivors often decline nPEP, and many who do take it do not complete the 28-day course. This pattern has been reported in several countries and several programs in North America. In Vancouver, 71 of 258 assault survivors accepted the 5-day starter pack of nPEP, 29 returned for additional doses, and eight completed 4 weeks of therapy (*96*). Those with the highest risk for HIV exposure (i.e., source known to be HIV infected, a homosexual or bisexual man, or an injection-drug user) were more likely to begin and complete nPEP.

Patients who have been sexually assaulted will benefit from supportive services to improve adherence to nPEP if it is prescribed, and from psychological and other support provided by sexual assault crisis centers. All sexually assaulted patients should be tested and administered prophylaxis for sexually transmitted infections (*85*), and women who might become pregnant should be offered emergency contraception (*122*).

Inmates

Certain illegal behaviors that result in imprisonment (e.g., prostitution and injection-drug use) also might be associated with a higher prevalence of HIV infection among prison inmates than among the general population (*119*). However, studies indicate that the risk for becoming infected in prison is probably less than the risk outside prison (*122–125*). However, when exposure does occur, because sexual contact and injection-drug use are prohibited in jails and prisons, prisoners who have experienced such exposures might be unable or unwilling to report the behaviors to health-care providers.

Administrators and health-care providers working in correctional settings should develop and implement systems to make HIV education and risk-reduction counseling, nPEP, voluntary HIV testing, and HIV care confidentially available to inmates. Such programs will allow inmates to benefit from nPEP when indicated, facilitate treatment services for those with drug addiction, and assist in the identification and treatment of sexual assault survivors.

Injection-Drug Users

A history of injection-drug use should not deter clinicians from prescribing nPEP if the exposure provides an opportunity to reduce the risk for consequent HIV infection. A survey of clinicians serving injection-drug users determined a high degree of willingness to provide nPEP after different types of potential HIV exposure (*126*).

In judging whether exposures are isolated, episodic, or ongoing, clinicians should consider that persons who continue to engage in risk behaviors (e.g., commercial sex workers or users of illicit drugs) might be practicing risk reduction (e.g., using condoms with every client, not sharing syringes, and using a new sterile syringe for each injection). Therefore, a high-risk exposure might represent an exceptional occurrence for such persons despite their ongoing risk behavior.

Injection-drug users should be assessed for their interest in substance abuse treatment and their knowledge and use of safe injection and sex practices. Patients desiring substance abuse treatment should be referred for such treatment. Persons who continue to inject or who are at risk for relapse to injection-drug use should be instructed in the use of a new sterile syringe for each injection and the importance of avoiding the sharing of injection equipment. In areas where programs are available, health-care providers should refer such patients to appropriate sources of sterile injection equipment.

Conclusion

Accumulated data from animal and human clinical and observational studies demonstrate that antiretroviral therapy initiated as soon as possible within 48–72 hours of sexual, injection-drug–use, and other substantial nonoccupational HIV exposure and continued for 28 days might reduce the likelihood of transmission. Because of these findings, DHHS recommends the prompt initiation of nPEP with HAART when persons seek care within 72 hours after exposure, the source is known to be HIV infected, and the exposure event presents a substantial risk for transmission. When the HIV

status of the source is not known and the patient seeks care within 72 hours after exposure, DHHS does not recommend for or against nPEP but encourages clinicians and patients to weigh the risks and benefits on a case-by-case basis. When the transmission risk is negligible or when patients seek care >72 hours after a substantial exposure, nPEP is not recommended; however, clinicians might consider prescribing nPEP for patients who seek care >72 hours after a substantial exposure if, in their judgment, the diminished potential benefit of nPEP outweighs the potential risk for adverse events from antiretroviral medications. These recommendations are intended for the United States and might not apply in other countries.

MMWR™

Morbidity and Mortality Weekly Report

Recommendations and Reports | January 21, 2005 / Vol. 54 / No. RR-2

Continuing Education Activity Sponsored by CDC

Antiretroviral Postexposure Prophylaxis After Sexual, Injection-Drug Use, or Other Nonoccupational Exposure to HIV in the United States

Recommendations from the U.S. Department of Health and Human Services

EXPIRATION — January 21, 2008

You must complete and return the response form electronically or by mail by **January 21, 2008**, to receive continuing education credit. If you answer all of the questions, you will receive an award letter for 2.0 hours Continuing Medical Education (CME) credit; 0.15 Continuing Education Units (CEUs); or 2.2 contact hours Continuing Nursing Education (CNE) credit. If you return the form electronically, you will receive educational credit immediately. If you mail the form, you will receive educational credit in approximately 30 days. No fees are charged for participating in this continuing education activity.

INSTRUCTIONS

By Internet

1. Read this *MMWR* (Vol. 54, RR-2), which contains the correct answers to the questions beginning on the next page.
2. Go to the *MMWR* Continuing Education Internet site at http://www.cdc.gov/mmwr/cme/conted.html.
3. Select which exam you want to take and select whether you want to register for CME, CEU, or CNE credit.
4. Fill out and submit the registration form.
5. Select exam questions. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
6. Submit your answers no later than **January 21, 2008**.
7. Immediately print your Certificate of Completion for your records.

By Mail or Fax

1. Read this *MMWR* (Vol. 54, RR-2), which contains the correct answers to the questions beginning on the next page.
2. Complete all registration information on the response form, including your name, mailing address, phone number, and e-mail address, if available.
3. Indicate whether you are registering for CME, CEU, or CNE credit.
4. Select your answers to the questions, and mark the corresponding letters on the response form. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
5. Sign and date the response form or a photocopy of the form and send no later than **January 21, 2008**, to
   Fax: 404-498-6035 Mail: MMWR CE Credit
   Division of Scientific Communications
   Coordinating Center for Health Information and Service, MS E-96
   Centers for Disease Control and Prevention
   1600 Clifton Rd, N.E.
   Atlanta, GA 30333
6. Your Certificate of Completion will be mailed to you within 30 days.

ACCREDITATION

Continuing Medical Education (CME). CDC is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians. CDC designates this educational activity for a maximum of 2.0 hours in category 1 credit toward the AMA Physician's Recognition Award. Each physician should claim only those hours of credit that he/she actually spent in the educational activity.

Continuing Education Unit (CEU). CDC has been approved as an authorized provider of continuing education and training programs by the International Association for Continuing Education and Training and awards 0.15 Continuing Education Units (CEUs).

Continuing Nursing Education (CNE). This activity for 2.2 contact hours is provided by CDC, which is accredited as a provider of continuing education in nursing by the American Nurses Credentialing Center's Commission on Accreditation.

DEPARTMENT OF HEALTH AND HUMAN SERVICES
CENTERS FOR DISEASE CONTROL AND PREVENTION

Goal and Objectives

This *MMWR* describes the potential risks and benefits of antiretroviral postexposure prophylaxis after nonoccupational exposures to human immunodeficiency virus (HIV). These recommendations were developed by CDC staff in collaboration with scientists, public health officials, clinicians, ethicists, members of affected communities, and representatives from professional associations and industry. The goal of this report is to provide information on which to base decisions regarding postexposure prophylaxis after a nonoccupational exposure to HIV. After completing this educational activity, the reader should be able to 1) describe the characteristics of a potential HIV exposure; 2) describe situations in which postexposure prophylaxis is most likely to be beneficial; 3) describe sources for obtaining information on antiretroviral regimens; and 4) describe appropriate follow-up schedules for persons who are prescribed antiretroviral postexposure prophylaxis.

To receive continuing education credit, please answer all of the following questions.

1. Evidence from controlled studies among humans indicates that the administration of antiretroviral postexposure prophylaxis after nonoccupational exposures to HIV is an effective means of preventing HIV infection.

A. True.
B. False.

2. On the basis of available evidence from animal studies, antiretroviral postexposure prophylaxis is most likely to be beneficial when initiated as soon as possible after exposure, and in the majority of cases, should not be initiated if >____ hours have elapsed since exposure.

A. 72.
B. 24.
C. 36.
D. None of the above.

3. Contact of which of the following body sites with HIV-infected bodily fluids constitutes a substantial HIV exposure?

A. Vagina.
B. Eye.
C. Intact skin.
D. Rectum.
E. A and D are correct.
F. A, B, and D are correct.

4. In a person with HIV infection, potentially infectious fluids include all of the following, except . . .

A. blood.
B. saliva visibly contaminated with blood.
C. urine not visibly contaminated with blood.
D. genital secretions.
E. none of the above; all are potentially infectious.

5. Which of the following lists of exposure types are correctly ordered from greatest risk of infection to least risk of infection?

A. Insertive anal is greater than insertive oral, which is greater than insertive vaginal.
B. Receptive anal is greater than receptive vaginal, which is greater than receptive oral.
C. Insertive anal is greater than receptive anal, which is greater than receptive oral.
D. None of the above.

6. The recommended duration of antiretroviral postexposure prophylaxis is . . .

A. 10 days.
B. 14 days.
C. 28 days.
D. none of the above.

7. Antiretroviral medications that should be avoided for pregnant women and women of childbearing potential include . . .

A. efavirenz.
B. nevirapine.
C. azidothymidine (AZT).
D. stavudine (D4T) in combination with didanosine (ddI).
E. A, B, and D.

8. Patients who are prescribed antiretroviral postexposure prophylaxis should be instructed about the symptoms of acute retroviral infection, which can include . . .

A. thrush.
B. fever.
C. rash.
D. all of the above.
E. B and C only.

9. Follow-up visits and testing of persons who are prescribed antiretroviral postexposure prophylaxis should be performed at approximately . . .

A. 4–6 weeks.
B. 3 months.
C. 6 months.
D. all of the above.

10. In addition to HIV antibody testing, follow-up laboratory testing of persons who are prescribed antiretroviral postexposure prophylaxis should include . . .

A. hepatitis A serology.
B. hepatitis B serology.
C. hepatitis C serology.
D. complete blood count, blood urea nitrogen/creatinine, and hepatic enzymes.
E. all of the above.
F. B, C, and D.

11. Which best describes your professional activities?

A. Physician.
B. Nurse.
C. Health educator.
D. Office staff.
E. Other.

12. I plan to use these recommendations as the basis for . . . (*Indicate all that apply.*)

A. health education materials.
B. insurance reimbursement policies.
C. local practice guidelines.
D. public policy.
E. other.

13. Each month, approximately how many patients with a potential HIV exposure do you treat?

A. None.
B. 1–5.
C. 6–20.
D. 21–50.
E. 51–100.
F. >100.

14. How much time did you spend reading this report and completing the exam?

A. <2.0 hours.
B. >2.0 hours but <3.0 hours.
C. >3.0 hours but <4.0.
D. >4.0 hours.

15. After reading this report, I am confident I can describe the characteristics of a potential HIV exposure.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

16. After reading this report, I am confident I can describe situations in which postexposure prophylaxis is most likely to be beneficial.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

17. After reading this report, I am confident I can describe sources for obtaining information on antiretroviral regimens.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

18. After reading this report, I am confident I can describe appropriate follow-up schedules for persons who are prescribed antiretroviral postexposure prophylaxis.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

MMWR Response Form for Continuing Education Credit
January 21, 2005/Vol. 54/No. RR-2

Antiretroviral Postexposure Prophylaxis After Sexual, Injection-Drug Use, or Other Nonoccupational Exposure to HIV in the United States
Recommendations from the U.S. Department of Health and Human Services

To receive continuing education credit, you must
1. provide your contact information;
2. indicate your choice of CME, CME for nonphysicians, CEU, or CNE credit;
3. answer all of the test questions;
4. sign and date this form or a photocopy;
5. submit your answer form by January 21, 2008.
Failure to complete these items can result in a delay or rejection of your application for continuing education credit.

19. The objectives are relevant to the goal of this report.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

20. The teaching strategies used in this report (text, figure, and tables) were useful.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

21. Overall, the presentation of the report enhanced my ability to understand the material.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

22. These recommendations will affect my practice.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

23. The content of this activity was appropriate for my educational needs.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

24. The availability of continuing education credit influenced my decision to read this report.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

25. How did you learn about this continuing education activity?

A. Internet.
B. Advertisement (e.g., fact sheet, *MMWR* cover, newsletter, or journal).
C. Coworker/supervisor.
D. Conference presentation.
E. *MMWR* subscription.
F. Other.

Correct answers for questions 1–10.
1. B, 2. A, 3. F, 4. C, 5. B, 6. C, 7. E, 8. D, 9. D, 10. F.

The *Morbidity and Mortality Weekly Report (MMWR)* Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available free of charge in electronic format and on a paid subscription basis for paper copy. To receive an electronic copy each week, send an e-mail message to *listserv@listserv.cdc.gov*. The body content should read *SUBscribe mmwr-toc*. Electronic copy also is available from CDC's World-Wide Web server at *http://www.cdc.gov/mmwr* or from CDC's file transfer protocol server at *ftp://ftp.cdc.gov/pub/publications/mmwr*. To subscribe for paper copy, contact Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone 202-512-1800.

Data in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the following Friday. Address inquiries about the *MMWR* Series, including material to be considered for publication, to Editor, *MMWR* Series, Mailstop E-96, CDC, 1600 Clifton Rd., N.E., Atlanta, GA 30333; telephone 888-232-3228.

All material in the *MMWR* Series is in the public domain and may be used and reprinted without permission; citation as to source, however, is appreciated.

All *MMWR* references are available on the Internet at http://www.cdc.gov/mmwr. Use the search function to find specific articles.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

References to non-CDC sites on the Internet are provided as a service to *MMWR* readers and do not constitute or imply endorsement of these organizations or their programs by CDC or the U.S. Department of Health and Human Services. CDC is not responsible for the content of these sites. URL addresses listed in *MMWR* were current as of the date of publication.

Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

August 16, 2010

Developed by the Panel on Antiretroviral Therapy
and Medical Management of HIV-Infected Children

François-Xavier Bagnoud Center, UMDNJ
The Health Resources and Services Administration
The National Institutes of Health

How to Cite the Pediatric Guidelines:
Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection. August 16, 2010; pp 1-219. Available at **http://aidsinfo.nih.gov/ContentFiles/PediatricGuidelines.pdf**. Accessed (insert date) [include page numbers, table number, etc. if applicable]

Use of antiretrovirals in pediatric patients is evolving rapidly.
These guidelines are updated regularly to provide current information.
The most recent information is available at **http://aidsinfo.nih.gov**.

What's New in the Pediatric Guidelines?

The updated *Guidelines for the Use of Antiretroviral Agents in Pediatric Infection* include the following changes made to the February 23, 2009, version of the guidelines. Key updates are also highlighted throughout the guidelines.

Ratings for Primary Recommendations

The key change prominent in the current guidelines is development of a ratings system to indicate strength and quality of evidence for each major recommendation. The strength of each recommendation is indicated by a letter (A = Strong, B = Moderate, C = Optional); the quality of the evidence supporting each recommendation is represented by a Roman numeral (I, II, III). In addition, because many pediatric recommendations will be based on data from clinical trials or observational studies in adults, with only safety and pharmacokinetic data in children, evidence ratings that are based on adult data will be indicated with an asterisk (*).

Format Changes/New Sections

Previous Appendix B: Characteristics of Available Antiretroviral Drugs and Supplement I: Pediatric Antiretroviral Drug Information

- Information in the previous Appendix B: Characteristics of Available Antiretroviral Drugs and pevious Supplement I: Pediatric Antiretroviral Drug Information of the February 23, 2009, guidelines has been combined into a new format with a table for each drug summarizing drug formulation, dosing recommendations, important adverse effects, and special instructions. Each table is followed by a short text section that includes important pediatric experience and references for that particular drug. Updated information on drugs is provided.

Previous Supplement III: Adverse Drug Effects

- This supplement to the previous version of the guidelines describes specific adverse drug effects observed in children, including lactic acidosis, hepatic toxicity, fat maldistribution and body habitus changes, hyperlipidemia, hyperglycemia, osteopenia, hematological complications, and hypersensitivity reactions and skin rashes. The supplement has been modified into a table format and included in the body of the current guidelines, with information on common causative drugs, estimated frequency of occurrence, timing of symptoms, risk factors, potential preventive measures, and suggested clinical management strategies and provides selected references regarding these toxicities in pediatric patients.

Previous Supplement II: Managing Complications of HIV Infection in HIV-Infected Children on Antiretroviral Therapy

- This supplement on pain management and nutrition included in the previous version of the guidelines has been retired. (See *Supplement II: Managing Complications of HIV Infection in HIV-Infected Children on Antiretroviral Therapy* in the archived February 23, 2009, *Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection* at **http://www.aidsinfo.nih.gov**.)

Key Updates

Updates to the various sections of the guidelines include the following new information/key changes:

Diagnosis of HIV Infection in Infants

- Viral diagnostic testing at birth is recommended for infants at high risk of HIV infection, such as infants born to HIV-infected mothers who did not receive prenatal care or prenatal antiretroviral therapy or who had HIV viral loads $\geq$1,000 copies/mL close to time of delivery (BIII). Viral diagnostic testing continues to be recommended for all HIV-exposed infants at age 14–21 days, 1–2 months, and 4–6 months (AII).

- An HIV qualitative RNA assay (APTIMA HIV-1 RNA Qualitative Assay) is an alternative diagnostic test that can be used for infant virologic diagnostic testing (AII).

When to Start

- Antiretroviral therapy continues to be recommended for all children younger than 12 months of age regardless of clinical, immunologic, or virologic symptoms (AI).
- However, whereas prior guidelines said antiretroviral therapy could be *considered* for asymptomatic or mildly symptomatic children with CD4 ≥25% (or ≥350 cells/uL if age ≥5 years) and HIV RNA ≥100,000 copies/mL, the current guidelines now *recommend* therapy in this situation (BII). Additionally, whereas prior guidelines recommended *deferral* of therapy for asymptomatic or mildly symptomatic children with CD4 ≥25% (or ≥350 cells/uL if age ≥5 years) and HIV RNA <100,000 copies/mL, the current guidelines say therapy can be *considered or deferred* (CIII). Specific recommendations are:
    - Initiation of antiretroviral therapy is *recommended* for children age ≥1 year with AIDS or significant symptoms (Clinical Category C or most Clinical Category B conditions), regardless of CD4 percentage/count or plasma HIV RNA level (AI*).
    - Initiation of antiretroviral therapy is also *recommended* for children age ≥1 year who have met the age-related CD4 threshold for initiating treatment (CD4 <25% for children 1 to <5 years of age (AII) and <350 cells/mm^3 for children ≥5 years of age (AI*), regardless of symptoms or plasma HIV RNA level).
    - Initiation of antiretroviral therapy is also *recommended* for children age ≥1 year who are asymptomatic or have mild symptoms (Clinical Categories N and A or the following Clinical Category B conditions: single episode of serious bacterial infection or lymphoid interstitial pneumonitis) *and* have CD4 ≥25% for children 1 to <5 years of age or ≥350 cells/mm^3 for children ≥5 years of age *and* have plasma HIV RNA ≥100,000 copies/mL (BII).
    - Initiation of antiretroviral therapy may be *considered or deferred* for children age ≥1 year who are asymptomatic or have mild symptoms and who have CD4 ≥25% for children 1 to <5 years of age and ≥350 cell/mm^3 for children ≥5 years of age *and* have plasma HIV RNA <100,000 copies/mL (CIII).

What Drugs to Start: Initial Combination Therapy for Antiretroviral-Naïve Children

- Recent data from clinical trials of nevirapine versus lopinavir/ritonavir-based therapy in children with single-dose nevirapine exposure for prevention of mother-to-child transmission of HIV are discussed.
- NNRTI-based therapy is not recommended for infants or children age <3 years with single-dose nevirapine exposure (AI).
- Darunavir in combination with low-dose ritonavir is now recommended as an alternative protease inhibitor for initial therapy in children age ≥6 years (AI*).
- Nelfinavir has been moved from an alternative protease inhibitor for initial therapy to a protease inhibitor for use in special circumstances in children age ≥2 years (AII).

Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents

- Results of several new studies regarding interventions to improve adherence in children and/or adolescents are described.

Additional Updates

- References have been updated in many sections.

Members of Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children

These updated *Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection* were developed by the Department of Health and Human Services (HHS) Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children convened by the National Resource Center at the François-Xavier Bagnoud Center (FXBC), University of Medicine and Dentistry of New Jersey (UMDNJ); the Health Resources and Services Administration (HRSA); and the National Institutes of Health (NIH).

Panel Co-Chairs:

Peter Havens, MS, MD	Medical College of Wisconsin, Milwaukee, WI
Russell Van Dyke, MD	Tulane University School of Medicine, New Orleans, LA
Geoffrey A. Weinberg, MD	University of Rochester School of Medicine and Dentistry, Rochester, NY

Panel Executive Secretary:

Lynne Mofenson, MD	National Institutes of Health, Rockville, MD

Members of the Panel:

Elaine J. Abrams, MD	Columbia University, New York, NY
Edmund Capparelli, MD	University of California – San Diego, La Jolla, CA
Diana Clarke, PharmD	Boston Medical Center, Boston, MA
Patricia M. Flynn, MD	St. Jude's Medical Center, Memphis, TN
Marc D. Foca, MD, MPH	Columbia University College of Physicians and Surgeons, New York, NY
Nancy Hutton, MD	Johns Hopkins School of Medicine, Baltimore, MD
Ebony Johnson, MHS	Children's National Medical Center, Washington DC
Paul A. Krogstad, MD	University of California – Los Angeles, Los Angeles, CA
James McAuley, MD, MPH	Rush University Medical Center, Chicago, IL
Mark Mirochnick, MD	Boston Medical Center, Boston, MA
Paul Palumbo, MD	Dartmouth Medical School, Dartmouth, NH
Mary E. Paul, MD	Baylor College of Medicine, Houston, TX
Vicki B. Peters, MD	New York City Department of Health and Mental Hygiene, New York, NY
Richard M. Rutstein, MD	Children's Hospital of Philadelphia, Philadelphia, PA
Dorothy Shaw, BA	Birmingham, AL
Andrew Wiznia, MD	Jacob Medical Center, Bronx, NY

Members from the Department of Health and Human Services:

Kenneth L. Dominguez, MD, MPH	Centers for Disease Control and Prevention, Atlanta, GA
Brian Feit, MPA	Health Resources and Services Administration, Rockville, MD
Edward Handelsman, MD	National Institutes of Health, Bethesda, MD
Rohan Hazra, MD	National Institutes of Health, Bethesda, MD
Patrick Jean-Philippe, MD	National Institutes of Health, Bethesda, MD
Linda Lewis, MD	Food and Drug Administration, Rockville, MD
George Siberry, MD, MPH	National Institutes of Health, Bethesda, MD

Nonvoting Observers from the François-Xavier Bagnoud Center:

Carolyn Burr, RN, EdD	François-Xavier Bagnoud Center, UMDNJ, Newark, NJ
Supriya Modey, MPH, MBBS	François-Xavier Bagnoud Center, UMDNJ, Newark, NJ
Andrea Norberg, MS, RN	AETC National Resource Center at the François-Xavier Bagnoud Center, UMDNJ, Newark, NJ
Deborah Storm, PhD	François-Xavier Bagnoud Center School of Nursing, UMDNJ, Newark, NJ

Introduction (Updated August 16, 2010)

These guidelines address issues specific to the use of antiretroviral therapy for HIV-infected infants, children, and prepubertal adolescents. Included is information on the management of adverse events of antiretroviral drugs in children and details on pediatric data related to antiretroviral agents. The Department of Health and Human Services (HHS) Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, a working group of the Office of AIDS Research Advisory Council (OARAC), reviews new data on an ongoing basis and provides regular updates to the guidelines. The guidelines are available on the AIDS*info* Web site at **http://aidsinfo.nih.gov**.

Separate sets of guidelines for the prevention and treatment of opportunistic infections in HIV-exposed and -infected children *[1]* and for the use of antiretroviral agents in HIV-infected postpubertal adolescents and adults *[2]* are also available on the AIDS*info* Web site. Because these guidelines were developed for the United States, they may not be applicable in other countries. The World Health Organization provides guidelines for resource-limited settings at **http://www.who.int/hiv/pub/arv/en.**

Since the development of the initial guidelines in 1993 (with the support of the François-Xavier Bagnoud Center [FXBC], University of Medicine and Dentistry of New Jersey [**http://www.fxbcenter.org**]), dramatic advances in medical management have followed the results of clinical trials of antiretroviral combination therapies in children. HIV mortality has decreased by more than 80%–90% since the introduction of protease inhibitor-containing combinations, and opportunistic and other related infections have significantly decreased in the era of highly active antiretroviral therapy (HAART) *[3-8]*. Advances including resistance testing and the ability to measure antiretroviral drug levels have enabled clinicians to more carefully choose very effective initial regimens while preserving selected drugs and drug classes for second- or third-line regimens. Therapeutic strategies continue to focus on early initiation of antiretroviral regimens capable of maximally suppressing viral replication to prevent disease progression, preserve immunologic function, and reduce the development of resistance. At the same time, availability of new drugs and drug formulations has led to regimens that improve adherence with less frequent dosing schedules. Improved monitoring and dosing schedules have also led to a decrease in drug failure due to toxicity. The use of antiretroviral therapy during pregnancy in HIV-infected women has resulted in a dramatic decrease in the transmission rate to infants, which is currently less than 2% in the United States, and the number of infants with AIDS in the United States continues to decline *[9]*. Finally, children living with HIV infection are, as a group, growing older, bringing new challenges of adherence, drug resistance, and management of multiple drugs.

Although the pathogenesis of HIV infection and the general virologic and immunologic principles underlying the use of antiretroviral therapy are similar for all HIV-infected people, there are unique considerations for HIV-infected infants, children, and adolescents, including:

- Acquisition of infection through perinatal exposure for many infected children;
- *In utero*, intrapartum, and/or postpartum neonatal exposure to zidovudine and other antiretroviral drugs in most perinatally infected children;
- Requirement for use of HIV virologic tests to diagnose perinatal HIV infection in infants younger than 18 months;
- Age-specific differences in CD4 cell counts;
- Changes in pharmacokinetic parameters with age caused by the continuing development and maturation of organ systems involved in drug metabolism and clearance;
- Differences in the clinical and virologic manifestations of perinatal HIV infection secondary to the occurrence of primary infection in growing, immunologically immature persons; and
- Special considerations associated with adherence to antiretroviral treatment for infants, children, and adolescents.

These recommendations represent the current state of knowledge regarding the use of antiretroviral drugs in children and are based on published and unpublished data regarding the treatment of HIV infection in infants,

children, adolescents, and adults and, when no definitive data were available, the clinical expertise of the Panel members. The Panel intends the guidelines to be flexible and not to replace the clinical judgment of experienced health care providers.

GUIDELINES DEVELOPMENT PROCESS

An outline of the composition of the Panel and the guidelines process can be found in Table 1.

Table 1. Outline of the Guidelines Development Process

Page 1 of 2

Topic	Comment
Goal of the Guidelines	Provide guidance to HIV care practitioners on the optimal use of antiretroviral agents in HIV-1-infected infants, children, and adolescents (through puberty) in the United States.
Panel members	The Panel is composed of approximately 25 voting members who have expertise in the management of HIV infection in infants, children, and adolescents. Members include representatives from the Committee on Pediatric AIDS of the American Academy of Pediatrics and community representatives with knowledge of pediatric HIV infection. The Panel also includes at least one representative from each of the following HHS agencies: Centers for Disease Control and Prevention (CDC), Food and Drug Administration (FDA), Health Resources and Services Administration (HRSA), and the National Institutes of Health (NIH). The U.S. government representatives are appointed by their respective agencies; nongovernmental members are selected after an open announcement to call for nominations. Each member serves on the Panel for a 3-year term with an option for reappointment. A list of current members can be found on **page viii** of this document.
Financial disclosure	All members of the Panel submit a written financial disclosure annually. A list of the latest disclosures can be found in **Appendix A** of this document.
Users of the guidelines	Providers of care to HIV-infected infants, children, and adolescents
Funding source	Office of AIDS Research, NIH
Evidence collection	The recommendations are generally based on studies published in peer-reviewed journals. On some occasions, particularly when new information may affect patient safety, unpublished data presented at major conferences or prepared by the FDA and/or manufacturers as warnings to the public may be used as evidence to revise the guidelines.
Recommendation grading	As described in **Table 2**.
Method of synthesizing data	Each section of the guidelines is assigned to a small group of Panel members with expertise in the area of interest. The members synthesize the available data and propose a recommendation to the Panel. All proposals are discussed at monthly teleconferences and then are voted on by the Panel members before being endorsed as official recommendations.

Topic	Comment
Other guidelines	These guidelines focus on HIV-infected infants, children, and adolescents through puberty. Separate guidelines outline the use of antiretroviral therapy in pregnant HIV-infected women and interventions for prevention of mother-to-child transmission, antiretroviral therapy for nonpregnant HIV-infected adults and postpubertal adolescents, and antiretroviral prophylaxis for those who experience occupational or nonoccupational exposure to HIV. These guidelines are also available at the AIDS*info* Web site (**http://www.aidsinfo.nih.gov**). These guidelines focus on HIV-infected children from infancy through puberty. For more detailed discussion on issues of treatment of postpubertal adolescents, the Panel defers to the designated expertise offered by the Panel on Antiretroviral Guidelines for Adults and Adolescents.
Update plan	The Panel meets monthly by teleconference to review data that may warrant modification of the guidelines. Updates may be prompted by new drug approvals (or new indications, formulations, or frequency of dosing), new significant safety or efficacy data, or other information that may have a significant impact on the clinical care of patients. For cases in which significant new data become available that may affect patient safety, a warning announcement with the Panel's recommendations may be made on the AIDS*info* Web site until appropriate changes can be made in the guidelines document. Updated guidelines are available at the AIDS*info* Web site (**http://www.aidsinfo.nih.gov**).
Public comments	A 2-week public comment period follows release of the updated guidelines on the AIDS*info* Web site. The Panel reviews comments received to determine whether additional revisions to the guidelines are indicated. The public may also submit comments to the Panel at any time at **contactus@aidsinfo.nih.gov**.

Basis for Recommendations

Recommendations in these guidelines are based upon scientific evidence and expert opinion. Each recommendation includes a letter (**A**, **B**, or **C**) that represents the strength of the recommendation and a Roman numeral (**I**, **II**, or **III**) that represents the quality of the evidence that supports the recommendation.

Because licensure of drugs in children often relies on efficacy data from adult trials in addition to safety and pharmacokinetic data in children, recommendations for antiretroviral drugs may need to rely on data from clinical trials or studies in adults. Pediatric drug approval may be based on evidence from adequate and well-controlled investigations in adults if:

(1) it is expected that the course of the disease and the effects of the drug are sufficiently similar in the pediatric and adult populations to permit extrapolation of adult efficacy data to pediatric patients;
(2) there are supplemental data on pharmacokinetics of the drug in children so that systemic exposure in adults and children are similar; and
(3) studies supporting the safety of the drug in pediatric patients are provided *[10]*.

In addition, if there was a concern that concentration-response relationships may be different in children, studies relating activity of the drug-to-drug levels (pharmacodynamic data) in children should be available.

In many cases, there is substantially greater evidence from adult studies (especially randomized clinical trials) than from pediatric studies related to use of antiretroviral drugs. Therefore, for pediatric recommendations, the following rationale has been used when the quality of evidence from pediatric studies is limited:

- **Quality of Evidence I—Randomized Clinical Trial Data.** In the absence of large pediatric randomized trials, adult data may be used if there are substantial pediatric data consistent with high-quality adult studies.
    - Quality of Evidence Rating I will be used if there are data from large randomized trials in children with clinical and/or validated laboratory endpoints.
    - Quality of Evidence Rating I* will be used if there are high-quality randomized clinical trial data in adults with clinical and/or validated laboratory endpoints and pediatric data from well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes that are consistent with the adult studies. For example, if a randomized Phase III clinical trial in adults demonstrates a drug is effective in antiretroviral-naïve patients and data from a nonrandomized pediatric trial demonstrate adequate and consistent safety and pharmacokinetic data in the pediatric population, a rating of I* may be used for quality of evidence.
- **Quality of Evidence Rating II—Nonrandomized Clinical Trials or Observational Cohort Data.** In the absence of large, well-designed, pediatric, nonrandomized trials or observational data, adult data may be used if there are sufficient pediatric data consistent with high-quality adult studies.
    - Quality of Evidence Rating II will be used if there are data from well-designed nonrandomized trials or observational cohorts in children.
    - Quality of Evidence Rating II* will be used if there are well-designed nonrandomized trials or observational cohort studies in adults with supporting and consistent information from smaller nonrandomized trials or cohort studies with clinical outcome data in children. For example, if a large observational study in adults demonstrates clinical benefit to initiating treatment at a certain CD4 cell count and observational data in children indicate that that a similar CD4 count is associated with clinical outcomes in children older than a specific age, a rating of II* may be used for quality of evidence.
- **Quality of Evidence Rating III—Expert opinion.** The criteria do not differ for adults and children.

Table 2. Rating Scheme for Recommendations

Strength of Recommendation	Quality of Evidence for Recommendation
A: Strong recommendation for the statement **B:** Moderate recommendation for the statement **C:** Optional recommendation for the statement	**I:** One or more randomized trials in children† with clinical outcomes and/or validated laboratory endpoints **I*:** One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children† from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes **II:** One or more well-designed, nonrandomized trials or observational cohort studies in children† with long-term clinical outcomes **II*:** One or more well-designed, nonrandomized trials or observational cohort studies in adults with long-term clinical outcomes with accompanying data in children† from one or more smaller nonrandomized trials or cohort studies with clinical outcome data **III:** Expert opinion

†Studies that include children or children/adolescents but not studies limited to postpubertal adolescents

CONCEPTS CONSIDERED IN THE FORMULATION OF PEDIATRIC TREATMENT GUIDELINES

The following concepts were considered in the formulation of these guidelines.

- Prenatal HIV testing and counseling should be the standard of care for all pregnant women in the United States *[11-13]*. Identification of HIV-infected women before or during pregnancy is critical to providing optimal therapy for both infected women and their infants and for reduction of perinatal transmission. Access to prenatal care is essential for all pregnant women.
- Enrollment of pregnant HIV-infected women; their HIV-exposed newborns; and infected infants, children, and adolescents into clinical trials offers the best means of determining safe and effective therapies.*
- The pharmaceutical industry and the federal government should continue collaboration that assures that drug formulations suitable for administration to infants and children are available for all antiretroviral drugs produced.
- Although some information regarding the efficacy of antiretroviral drugs for children can be extrapolated from clinical trials involving adults, concurrent clinical trials for children are needed to determine the impact of the drug on specific manifestations of HIV infection in children, including growth, development, and neurologic disease. However, the absence of Phase III efficacy trials addressing pediatric-specific manifestations of HIV infection does not preclude the use of any approved antiretroviral drug in children.

* In areas where enrollment in clinical trials is possible, enrolling the child in available trials should be discussed with the caregivers of the child. Information about clinical trials for HIV-infected adults and children can be obtained from the AIDS*info* Web site (**http://aidsinfo.nih.gov/ClinicalTrials/**) or by telephone at 1-800-448-0440.

- Treatment of HIV infection in infants, children, and adolescents is rapidly evolving and becoming increasingly complex; therefore, wherever possible, their treatment should be managed by a specialist in pediatric and adolescent HIV infection. If this is not possible, such experts should be consulted.
- Effective management of the complex and diverse needs of HIV-infected infants, children, adolescents, and their families requires a multidisciplinary team approach that includes physicians, nurses, nutritionists, pharmacists, dentists, psychologists, social workers, and outreach workers.
- Health care providers considering antiretroviral treatment for infants, children, or adolescents should consider certain factors influencing adherence to therapy, including:
    - availability and palatability of drug formulations;
    - impact of the medication schedule on quality of life, including number of medications, frequency of administration, ability to coadminister with other prescribed medications, and need to take with or without food;
    - ability of the child's caregiver or the adolescent to administer complex drug regimens and availability of resources that might be effective in facilitating adherence; and
    - potential for drug interactions.
- The choice of initial antiretroviral regimen should include consideration of factors that may limit future treatment options, such as the presence of or potential for the development of antiretroviral resistance. HIV resistance assays have proven useful in guiding initial therapy and in changing failing regimens, but expert clinical interpretation is required.
- Monitoring growth and development, short- and long-term drug toxicities, neurodevelopment, symptom management, and nutrition are all essential in the care of HIV-infected children because they may significantly influence quality of life.

Identification of Perinatal HIV Exposure

(Updated August 16, 2010)

Panel's Recommendations:

- ***Universal counseling and voluntary HIV testing early in pregnancy, including opt-out testing, are recommended as standard of care for all pregnant women in the United States (AII).***
- ***Repeat HIV testing is recommended in the third trimester for women who have negative HIV antibody tests earlier in pregnancy if they are at high risk of HIV infection because of behavior or residence in a high-prevalence area (AII).***
- ***Women seen at labor with undocumented HIV status should undergo rapid HIV antibody testing, and women with a positive antibody test should initiate intrapartum antiretroviral prophylaxis (AII).***
- ***If acute HIV infection is suspected in a pregnant woman, a virologic test (e.g., plasma HIV RNA assay) should be performed because serologic testing may be negative at this early stage of infection (AII).***
- ***Women who have not been tested for HIV prior to or during labor should be offered rapid HIV antibody testing during the immediate postpartum period or their newborns should undergo rapid HIV antibody testing; if the mother or infant is HIV antibody positive, infant antiretroviral prophylaxis should be initiated as soon as possible and the mother advised not to breastfeed pending results of confirmatory HIV antibody testing (AII).***

Appropriate treatment of HIV-infected infants requires HIV-exposed infants to be identified as soon as possible, which can be best accomplished through the identification of HIV-infected women before or during pregnancy. Universal HIV counseling and voluntary HIV testing, including consent using an opt-out approach, are recommended as the standard of care for all pregnant women in the United States by the Panel, the U.S. Public Health Service (USPHS), the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists, and the U.S. Preventive Services Task Force *[1-6]*. An opt-out approach notifies a pregnant woman that HIV testing will be performed as part of routine care unless she chooses not to be tested for HIV *[7]*.

Early identification of HIV-infected women is crucial for their health and for the care of HIV-exposed and HIV-infected children. Knowledge of antenatal maternal HIV infection enables:

- HIV-infected women to receive appropriate antiretroviral therapy and prophylaxis against opportunistic infections for their own health;
- Provision of antiretroviral chemoprophylaxis during pregnancy, during labor, and to the newborn to reduce the risk of HIV transmission from mother to child *[8]*;
- Counseling of HIV-infected women about the indications for and potential benefits of scheduled cesarean section delivery to reduce perinatal HIV transmission *[8-11]*;
- Counseling of HIV-infected women about the risks of HIV transmission through breast milk and advising against breastfeeding in the United States and other countries where safe alternatives to breast milk are available *[12]*;
- Initiation of prophylaxis against *Pneumocystis jiroveci* pneumonia (PCP) in all HIV-exposed infants with indeterminate HIV infection status or who have documented HIV infection beginning at age 4 to 6 weeks *[13]*; and
- Early diagnostic evaluation of HIV-exposed infants to permit early initiation of antiretroviral therapy in infected infants *[2, 14]*.

REPEAT HIV TESTING IN THE THIRD TRIMESTER

Repeat HIV testing is recommended in the third trimester, preferably <36 weeks gestation, for women with initially negative HIV antibody tests who are at high risk of HIV infection and may be considered for all pregnant women. A second HIV test during the third trimester is recommended for women who meet 1 or more of the following criteria: women who receive health care in jurisdictions with elevated incidence of HIV or AIDS among women 15–45 years of age; women who receive health care in facilities in which prenatal screening identifies at least 1 HIV-infected pregnant woman per 1,000 women screened; women who are known to be at high risk of acquiring HIV (e.g., injection drug users or partners of injection drug users, women who exchange sex for money or drugs, women who are sex partners of HIV-infected persons, and women who have had a new or more than 1 sex partner during this pregnancy or diagnosis of a new sexually transmitted infection during pregnancy); and women who have signs or symptoms of acute HIV infection *[3-4, 15]*. Women who have declined testing earlier in pregnancy should have testing offered again during the third trimester. There is evidence that the risk of HIV acquisition may be significantly higher during pregnancy than in the postpartum period *[16]*. If acute HIV infection is suspected, a virologic test (e.g., plasma HIV RNA assay) should be performed because serologic testing may be negative at this early stage of infection.

RAPID HIV TESTING DURING LABOR IN WOMEN WITH UNKNOWN HIV STATUS

Use of rapid test kits or an expedited enzyme-linked immunosorbant assay (ELISA) to detect HIV antibody is recommended to screen women who are seen at labor and have undocumented HIV status in order to identify HIV exposure in their infants *[2-4, 14]*. Any hospital offering intrapartum care should have rapid HIV testing available and should have in place policies and procedures to assure that staff are prepared to provide patient education about rapid HIV testing, that appropriate antiretroviral medications are available whenever needed, and that follow-up procedures for women found to be HIV infected and their infants are in place. Rapid tests have been found to be feasible, accurate, timely, and useful both in providing prompt access to intrapartum and neonatal antiretroviral prophylaxis and in reducing perinatal HIV transmission *[17]*. Results of rapid tests can be obtained within minutes to a few hours and are as accurate as standard ELISA antibody testing *[18-19]*. A positive rapid HIV test result must be followed by a confirmatory test such as a Western blot (or immunofluorescent antibody [IFA]); a standard ELISA should not be used as a confirmatory test for a rapid HIV antibody test *[19]*. A negative single rapid test does not need confirmation. The immediate initiation of antiretroviral prophylaxis for prevention of mother-to-child transmission of HIV is strongly recommended while awaiting confirmatory testing results after an initial positive rapid HIV test *[2, 6, 8, 14]*.

HIV COUNSELING AND TESTING DURING POSTNATAL PERIOD

Women who have not been tested for HIV prior to or during labor should be offered rapid testing during the immediate postpartum period or their newborns should undergo rapid HIV antibody testing, with counseling and consent of the mother unless state law allows testing without consent *[3, 8, 20-21]*. Because neonatal antiretroviral chemoprophylaxis should be initiated as soon as possible after birth to be effective in preventing mother-to-child transmission, use of rapid HIV antibody assays or expedited ELISA testing to allow prompt identification of HIV-exposed infants is critical. It is strongly recommended that infant antiretroviral prophylaxis be initiated while awaiting confirmatory testing results after an initial positive rapid test in the mother or the infant, and women with positive rapid HIV test results should be advised not to initiate breastfeeding pending results of confirmatory testing. If the confirmatory test is negative, the infant antiretroviral prophylaxis can be discontinued and the mother can initiate breastfeeding. Mechanisms should be developed to facilitate rapid HIV screening for infants who have been abandoned and are in the custody of the state.

Diagnosis of HIV Infection in Infants

(Updated August 16, 2010)

Panel's Recommendations:

- ***Virologic assays that directly detect HIV must be used to diagnose HIV infection in infants younger than 18 months, because maternal HIV antibody may persist in this age group and give a false-positive antibody test in an uninfected child (AII).***
- ***Virologic diagnostic testing in infants with known perinatal HIV exposure is recommended at age 14–21 days; 1–2 months; and 4–6 months (AII).***
- ***Virologic diagnostic testing at birth should be considered for infants at high risk of HIV infection (BIII).***
- ***HIV DNA PCR and HIV RNA assays are recommended as preferred virologic assays (AII).***
- ***Confirmation of HIV infection should be based on two positive virologic tests from separate blood samples (AI).***
- ***Definitive exclusion of HIV infection should be based on at least two negative virologic tests (one at ≥1 month and one at ≥4 months of age) (AII).***
- ***Some experts confirm the absence of HIV infection at 12–18 months of age in infants with prior negative virologic tests by performing an antibody test to document loss of HIV antibody (BIII).***
- ***In children age ≥18 months, HIV antibody assays alone can be used for diagnosis (AII).***

CHOICE OF DIAGNOSTIC TEST

HIV infection can be definitively diagnosed through the use of virologic assays in most nonbreastfed HIV-infected infants by 1 month of age and in virtually all infected infants by 4 months of age. Tests for antibodies to HIV, including newer rapid tests, do not establish the presence of HIV infection in infants because of transplacental transfer of maternal antibodies; therefore a virologic test should be used *[1]*. A positive virologic test (i.e., detection of HIV by DNA polymerase chain reaction [PCR] or RNA assays) indicates likely HIV infection and should be confirmed by a repeat virologic test on a second specimen as soon as possible after the first test result becomes available. HIV culture is not used for routine HIV diagnostic testing. The use of the currently approved HIV p24 antigen assay is not recommended for infant diagnosis in the United States because the sensitivity and specificity of the assay in the first months of life are less than that of other HIV virologic tests *[2-3]*.

HIV DNA PCR

HIV DNA PCR is a sensitive technique used to detect specific HIV viral DNA in a patient's peripheral blood mononuclear cells (PBMCs). The sensitivity of a single HIV DNA PCR test performed at <48 hours of age is less than 40% but increases to more than 90% by 2–4 weeks of age *[4-8]*.

In a meta-analysis, 38% (90% confidence interval [CI] = 29%–46%) of infected children had positive HIV DNA PCR tests by 48 hours of age *[9]*. No substantial change in sensitivity during the first week of life was observed, but sensitivity increased rapidly during the second week, with 93% of infected children (90% CI = 76%–97%) testing positive by HIV DNA PCR by age 14 days. By age 28 days, HIV DNA PCR had 96% sensitivity and 99% specificity to identify HIV proviral DNA in PBMCs.

HIV RNA Assays

HIV quantitative RNA assays detect extracellular viral RNA in the plasma and are as sensitive as HIV DNA PCR for early diagnosis of HIV infection in HIV-exposed infants. Studies have demonstrated sensitivities of 25%–40% during the first weeks of life, increasing to 90%–100% by 2–3 months of age *[7-8, 10-16]*. Similarly, specificity is comparable between the two tests, although the detection of low levels of HIV RNA

(<5,000 copies/mL) may not be reproducible and tests with low levels of HIV RNA should be repeated before they are interpreted as documenting the presence of HIV infection in an infant. An HIV RNA assay can be used as the confirmatory test for infants who have an initial positive HIV DNA PCR test. In addition to providing virologic confirmation of infection status, the expense of repeat HIV DNA PCR testing is spared and an HIV RNA measurement is available to assess baseline viral load. HIV RNA assays may be more sensitive than HIV DNA PCR for detecting HIV non-subtype B (see HIV subtype section below). However, although HIV DNA PCR remains positive even in individuals receiving highly active antiretroviral therapy *[17]*, it is unknown whether the sensitivity of RNA assays might be affected by maternal antenatal treatment with combination antiretroviral drugs and/or infant antiretroviral prophylaxis.

HIV qualitative RNA assay (APTIMA HIV-1 RNA Qualitative Assay) is an alternative diagnostic test that can be used for infant testing *[18-21]*.

HIV Culture

HIV culture is not used for routine HIV diagnostic testing. It is generally not available outside of research laboratories. Although HIV culture has a sensitivity similar to that of HIV DNA PCR *[22]*, it is more complex and expensive to perform than DNA PCR or RNA assays and may require 2–4 weeks for definitive results.

ISSUES RELATED TO DIAGNOSIS OF NON-SUBTYPE B HIV INFECTION

Although HIV subtype B is the predominant viral subtype found in the United States, non-subtype B viruses predominate in some other parts of the world, such as subtype C in regions of Africa and India and subtype CRF01 in much of Southeast Asia *[23-25]*. Currently available HIV DNA PCR tests are less sensitive in the detection of non-subtype B HIV, and false-negative HIV DNA PCR assays have been reported in infants infected with non-subtype B HIV *[26-29]*. In an evaluation of perinatally infected infants diagnosed in New York State in 2001–2002, 16.7% of infants were infected with a non-subtype B strain of HIV, compared with 4.4% of infants diagnosed between 1998 and 1999 *[30]*.

Some of the currently available HIV RNA assays have improved sensitivity for detection of non-subtype B HIV infection *[31-34]*, although even these assays may not detect or properly quantify some non-B subtypes, particularly the more uncommon group O HIV subtypes *[33, 35-36]*. When non-subtype B perinatal exposure is suspected in infants with negative HIV DNA PCR, repeat testing using one of the newer RNA assays shown to be more sensitive in the detection of non-subtype B HIV is recommended (e.g., Amplicor HIV-1 Monitor 1.5 [Roche Molecular Systems, Pleasanton, CA], NucliSens HIV-1 QT [bioMerieux, Inc., Durham, NC], Versant Quantiplex HIV RNA 3.0 [bDNA] [Bayer Corporation, Tarrytown, NY]; AmpliPrep/TaqMan HIV-1 Test [Roche Diagnostics, Indianapolis, IN]; Real Time HIV-1 Assay [Abbott Molecular Incorporated, Des Plaines, IL] and the APTIMA HIV-1 RNA Qualitative Assay [Gen-Probe Incorporated San Diego, CA]).

When evaluating an infant whose mother and/or father comes from an area endemic for non-subtype B HIV, such as Africa and Southeast Asia, clinicians should consider conducting initial testing using one of the assays more sensitive for non-subtype B virus (for example, one of the newer RNA assays mentioned above) *[33, 37]*. In a child with negative HIV DNA PCR and RNA assays but in whom non-subtype B infection is suspected, the clinician should consult with an expert in pediatric HIV infection and the child should undergo close clinical monitoring and definitive HIV serologic testing at age 18 months.

TIMING OF DIAGNOSTIC TESTING IN INFANTS WITH KNOWN PERINATAL HIV EXPOSURE

Virologic diagnostic testing of the HIV-exposed infant should be performed at age 14–21 days, at age 1–2 months, and at age 4–6 months. Virologic diagnostic testing at birth should be considered for infants at high risk of HIV infection.

HIV infection is diagnosed by two positive HIV virologic tests performed on separate blood samples, regardless of child's age. A positive HIV antibody test with confirmatory Western blot (or IFA) at age ≥18 months confirms HIV infection with the exception of rare late seroreverters (see HIV antibody section below) *[1]*.

HIV infection can be *presumptively* excluded in nonbreastfed infants with two or more negative virologic tests, with one test obtained at ≥14 days of age and one obtained at ≥1 month of age; or one negative virologic test result obtained at ≥2 months of age; or one negative HIV antibody test result obtained at ≥6 months of age *[1, 38]*. *Pneumocystis jiroveci* pneumonia (PCP) prophylaxis is recommended for infants with indeterminate HIV infection status starting at 4–6 weeks of age until they are determined to be HIV uninfected or *presumptively* uninfected with HIV *[39]*. Thus, initiation of PCP prophylaxis can be avoided or, if prophylaxis was initiated, can be stopped, if the infant has negative virologic tests at 2 weeks of age and at 1 month of age, or if virologic testing is negative at or beyond 2 months of age. *Definitive* exclusion of HIV infection in a nonbreastfed infant is based on two or more negative virologic tests, with one obtained at ≥1 month of age and one at ≥4 months of age, or two negative HIV antibody tests from separate specimens obtained at ≥6 months of age. For both *presumptive* and *definitive* exclusion of HIV infection, the child must have no other laboratory (e.g., no positive virologic test results or low CD4 count/percent) or clinical evidence of HIV infection. Many experts confirm the absence of HIV infection in infants with negative virologic tests by performing an antibody test at 12–18 months of age to document seroreversion to HIV antibody negative status.

Virologic Testing at Birth (Optional)

Virologic testing at birth may be considered for newborns at high risk of HIV infection, such as infants born to HIV-infected mothers who did not receive prenatal care, prenatal antiretroviral therapy, or who had HIV viral loads ≥1,000 copies/mL close to time of delivery. As many as 30%–40% of HIV-infected infants can be identified by 48 hours of age *[4, 9]*. Blood samples from the umbilical cord should not be used for diagnostic evaluations due to the potential contamination with maternal blood. Working definitions have been proposed to differentiate acquisition of HIV infection during the intrauterine period from the intrapartum period. Infants who have a positive virologic test at or before age 48 hours are considered to have early (i.e., intrauterine) infection, whereas infants who have a negative virologic test during the first week of life and subsequent positive tests are considered to have late (i.e., intrapartum) infection *[40]*. Some researchers have proposed that infants with early infection may have more rapid disease progression than those with late infection and therefore should receive more aggressive therapy *[40-41]*. However, data from prospective cohort studies have demonstrated that although early differences in HIV RNA levels were present between infants with a positive HIV culture within 48 hours of birth and those with a first positive culture after 7 days of age, these differences were no longer statistically significant after 2 months of age *[42]*. HIV RNA levels after the first month of life were more predictive of rapid disease progression than the time at which HIV culture tests were positive *[42]*.

Virologic Testing at Age 14–21 Days

The diagnostic sensitivity of virologic assays increases rapidly by age 2 weeks *[9]*, and early identification of infection would permit discontinuation of neonatal antiretroviral prophylaxis and further evaluation for initiation of combination antiretroviral therapy (see **When to Initiate Therapy in Antiretroviral-Naïve HIV-Infected Infants Younger than 12 Months** and **Table 7**).

Virologic Testing at Age 1–2 Months

Infants with negative virologic tests before 1 month of age should be retested at 1–2 months of age. Most HIV-exposed neonates will receive 6 weeks of neonatal antiretroviral prophylaxis. Although antiretroviral agents could theoretically affect the predictive value of HIV virologic testing in neonates, the use of antepartum/intrapartum/neonatal zidovudine single-drug prophylaxis did not delay the detection of HIV by culture in infants in PACTG protocol 076 and has not decreased the sensitivity and predictive values of many virologic assays *[10, 12-13, 16, 38, 43-44]*. The affect of prenatal and neonatal combination antiretroviral regimens on the sensitivity of virologic tests for HIV-exposed infants needs to be examined. An infant with two negative virologic tests, one at ≥14 days and one at ≥1 month of age can be viewed as *presumptively* uninfected and would not need to initiate PCP prophylaxis, assuming the child has no laboratory (e.g., no positive virologic test results or low CD4 count) or clinical evidence of HIV infection.

Virologic Testing at Age 4–6 Months

HIV-exposed children who have had repeatedly negative virologic assays at 14–21 days of age and at 1–2 months of age should be retested at 4–6 months of age for *definitive* exclusion of HIV infection.

Antibody Testing at Age 6 Months or Older

Two or more negative HIV antibody tests performed at ≥6 months of age can also be used to *definitively* exclude HIV infection in HIV-exposed children with no clinical or virologic laboratory evidence of HIV infection.

Antibody Testing at Age 12–18 Months to Document Seroreversion

Many experts confirm the absence of HIV infection in infants with negative virologic tests by performing serology repeated between ages 12–18 months to confirm that maternal HIV antibodies transferred to the infant *in utero* have disappeared, if there has not been previous confirmation of two negative antibody tests. Although the proportion of infants who serorevert between 15 and 18 months of age is close to 100%, as many as 95% of infants may serorevert by 12 months of age; factors that might influence the time to seroreversion include the staging of maternal disease or the sensitivity of the assay *[1, 45-48]*.

Antibody Testing at Age 18 Months or Older

HIV infection can be diagnosed in children 18 months of age or older with a positive HIV antibody test and a confirmatory Western blot (or IFA). On rare occasions, nonbreastfed HIV-exposed infants with no other route of HIV transmission (e.g., sexual abuse or receipt of solid food premasticated by an HIV-1–infected caregiver) and no prior clinical or virologic laboratory evidence of HIV infection may have residual antibody at 18 months of age. These infants should have monthly repeat antibody testing because they may be late seroreverters, as late as 24 months *[48]*.

Laboratory Monitoring of Pediatric HIV Infection (Updated August 16, 2010)

***Panel's Recommendations*:**

- ***The age of the child must be considered when interpreting the risk of disease progression based on CD4 percentage or count and plasma HIV RNA level (AII). For any given CD4 percentage or count, younger children, especially those in the first year of life, face higher risk of progression than do older children.***
- ***In children younger than 5 years of age, CD4 percentage is preferred for monitoring immune status because of age-related changes in absolute CD4 count in this age group (AII).***
- ***CD4 percentage or count should be measured at the time of diagnosis of HIV infection and at least every 3–4 months thereafter (AIII).***
- ***Plasma HIV RNA should be measured to assess viral load at the time of diagnosis of HIV infection and at least every 3–4 months thereafter (AIII).***
- ***More frequent CD4 cell and plasma HIV RNA monitoring should be considered in infants younger than 6–12 months of age; in children with suspected clinical, immunologic, or virologic deterioration; to confirm an abnormal value; or when initiating or changing therapy (AIII).***
- ***An ultrasensitive viral load assay should be used to confirm that antiretroviral therapy is producing maximal suppression of viremia (AIII).***

IMMUNOLOGIC MONITORING IN CHILDREN

Clinicians interpreting CD4 count for children must consider age as a variable. CD4 count and percentage values in healthy infants who are not infected with HIV are considerably higher than values observed in uninfected adults and slowly decline to adult values by age 5 years *[1-2]*. In children younger than 5 years of age, the absolute CD4 count tends to vary more with age within an individual child than does CD4 percentage. Therefore, in HIV-infected children younger than 5 years of age, CD4 percentage is preferred for monitoring immune status, whereas absolute CD4 count can be used in older children *[3-5]*.

In HIV-infected children, as in infected adults, the CD4 count and percentage decline as HIV infection progresses, and patients with lower CD4 values have a poorer prognosis than patients with higher values (**Tables 3–5**). Consequently, CD4 values should be obtained as soon as possible after a child has a positive test for HIV and subsequently every 3–4 months. Increased frequency of evaluations may be needed for children with suspected clinical, immunologic, or virologic deterioration; to confirm an abnormal value; or when initiating or changing therapy. Because young infants with HIV infection may have rapid disease progression *[6-7]*, some experts monitor CD4 percentage more frequently (e.g., every 1–2 months) in untreated infants younger than 6 to 12 months of age. Because of the risk of rapid progression, initiation of antiretroviral treatment is now recommended for all HIV-infected infants younger than 12 months of age (see **When to Initiate Therapy in Antiretroviral-Naïve Children**). For adolescents who are adherent to therapy with sustained viral suppression and stable clinical status for more than 2–3 years, some experts monitor CD4 counts and HIV RNA levels less frequently.

The prognostic value of CD4 percentage and HIV RNA copy number was assessed in a large individual patient meta-analysis (the HIV Pediatric Prognostic Markers Collaborative Study), which incorporated clinical and laboratory data from 17 pediatric studies and included 3,941 HIV-infected children receiving either no therapy or only zidovudine monotherapy *[4]*. The analysis looked at the short-term (12-month) risk of developing AIDS or death based on the child's age and selected values of CD4 percentage and HIV RNA copy number at baseline. **Figures 1 and 2** and **Table 3** depict age-associated 1-year risk of developing AIDS or death as a function of CD4 percentage. In a separate analysis of this data set, predictive value of absolute CD4 cell count for risk of death or AIDS/death in HIV-infected children 5 years of age or older was similar to that observed in

young adults, with an increase in the risk of mortality when CD4 cell count fell less than 350 cells/mm^3 (**Table 4** and **Figure 3**) *[3, 8]*.

The risk of disease progression associated with a specific CD4 percentage or count varies with the age of the child. Infants in the first year of life experience higher risks of progression or death than older children for any given CD4 stratum. For example, comparing a 1-year-old child with CD4 percentage of 25% to a 5-year-old child with the same CD4 percentage, there is an approximately fourfold increase in the risk of AIDS and sixfold increase in the risk of death in the 1-year-old child (**Figures 1 and 2**). Children 5 years of age or older have a lower risk of progression than younger children, with the increase in risk of AIDS or death corresponding to absolute CD4 levels more similar to those in young adults (**Figure 3**). In the HIV Pediatric Prognostic Marker Collaborative Study, there were no deaths among children 5 years of age or older with CD4 count greater than 350 cells/mm^3, although in younger children there continued to be a significant risk of death even with a CD4 cell count greater than 500 cells/mm^3 (**Table 4**).

These risk profiles form the rationale for recommendations on when to initiate therapy in a treatment-naïve HIV-infected child (see **When to Initiate Therapy in Antiretroviral-Naïve Children**). A Web site using the meta-analysis from the HIV Pediatric Prognostic Markers Collaborative Study (HPPMCS) is available to estimate the short-term risk of progression to AIDS or death in the absence of effective antiretroviral therapy according to age and the most recent CD4 percentage or HIV-1 RNA viral load measurement (**http://hppmcs.org**) *[4]*.

Measurement of CD4 values can be associated with considerable intrapatient variation *[5]*. Even mild intercurrent illness or the receipt of vaccinations can produce a transient decrease in CD4 count and percentage; thus, CD4 values are best measured when patients are clinically stable. No modification in therapy should be made in response to a change in CD4 values until the change has been substantiated by at least a second determination, with a minimum of 1 week between measurements.

HIV RNA MONITORING IN CHILDREN

Viral burden in peripheral blood can be determined by using quantitative HIV RNA assays. During the period of primary infection in adults, HIV RNA copy number initially rises to high peak levels and then declines by as much as 2–3 $\log_{10}$ copies to reach a stable lower level (the virologic set point) approximately 6–12 months following acute infection *[9-10]*. In infected adults, the viral set point correlates with the subsequent risk of disease progression or death *[11-12]*. On the basis of data from studies in infected adults, recommendations for the use of HIV RNA copy number in managing antiretroviral therapy have been developed for adults *[13]*. These recommendations also are applicable to infected adolescents.

The HIV RNA pattern in perinatally infected infants differs from that in infected adults and adolescents. High HIV RNA copy numbers persist in infected children for prolonged periods *[14-15]*. In one prospective study, HIV RNA levels generally were low at birth (i.e., <10,000 copies/mL), increased to high values by age 2 months (most infants had values >100,000 copies/mL, ranging from undetectable to nearly 10 million copies/mL), and then decreased slowly; the mean HIV RNA level during the first year of life was 185,000 copies/mL *[16]*. Additionally, in contrast to the adult pattern, after the first year of life, HIV RNA copy number slowly declines over the next few years *[16-19]*. This pattern probably reflects the lower efficiency of an immature, but developing, immune system in containing viral replication and possibly the rapid expansion of HIV-susceptible cells that occurs with somatic growth *[20]*.

High HIV RNA levels (i.e., >299,000 copies/mL) in infants age <12 months have been correlated with disease progression and death, but RNA levels overlap considerably in young infants who have rapid disease progression and those who do not *[14, 16]*. High RNA levels (i.e., levels of >100,000 copies/mL) in older children have also been associated with high risk of disease progression and mortality, particularly if CD4 percentage is <15% (**Table 5**) *[18-19]*. The most robust data set available to elucidate the predictive value of plasma RNA for disease progression in children was assembled in the HIV Pediatric Prognostic Markers Collaborative Study (see **Immunologic Monitoring in Children**) *[4]*. As for CD4 percentage, analyses were performed for age-associated risk in the context of plasma RNA levels in a cohort of children receiving either

no therapy or only zidovudine monotherapy. Similar to data from previous studies *[18-19]*, the risk of clinical progression to AIDS or death dramatically increases when HIV RNA exceeds 100,000 copies (5.0 $\log_{10}$ copies)/mL; at lower values, only older children show much variation in risk (**Figures 4 and 5** and **Table 3**). At any given level of HIV RNA, infants younger than 1 year of age were at higher risk of progression than older children, although these differences were less striking than those observed for the CD4 percentage data.

Despite data indicating that high plasma HIV RNA concentrations are associated with disease progression, the predictive value of specific HIV RNA concentrations for disease progression and death for an individual child is moderate *[18]*. HIV RNA concentration may be difficult to interpret during the first year of life because values are high and are less predictive of disease progression risk than in older children *[15]*. In both HIV-infected children and adults, CD4 percentage or count and HIV RNA copy number are independent predictors of disease progression and mortality risk, and use of the two markers together more accurately defines prognosis *[18-19, 21-23]*.

HIV RNA copy number should be assessed as soon as possible after a child has a positive virologic test for HIV and every 3–4 months thereafter; increased frequency of evaluations may be needed for children experiencing virologic, immunologic, or clinical deterioration; to confirm an abnormal value; or when initiating or changing antiretroviral therapy (see **Antiretroviral Treatment Failure in Infants, Children, and Adolescents**). Because young infants with HIV infection may have rapid disease progression, some experts monitor HIV RNA concentration more frequently (e.g., every 1–2 months) in untreated infants younger than 6–12 months of age.

Methodological Considerations in Interpretation and Comparability of HIV RNA Assays

The use of HIV RNA assays for clinical purposes requires specific considerations *[24]*, which are discussed more completely elsewhere *[13]*. Several different methods can be used for quantitating HIV RNA, each has a different level of sensitivity. Although the results of the assays are correlated, the absolute HIV RNA copy number obtained from a single specimen tested by two different assays can differ by twofold (0.3 $\log_{10}$ units) or more *[25-28]*.

There are currently five FDA-approved viral load assays using one of three different methodologies:

- HIV-1 reverse transcriptase (RT) quantitative PCR assays: the Amplicor HIV-1 Monitor Test, version 1.5 (Roche Diagnostics), for which the lower limit of detection differs between the "ultrasensitive" assay (<50 copies/mL) and the "regular sensitivity" assay (<400 copies/mL); the AmpliPrep/TaqMan HIV-1 Test (Roche Diagnostics); and the Real Time HIV-1 Assay (Abbott Molecular Incorporated);
- HIV-1 nucleic acid sequence-based amplification test (NucliSens HIV-1 QT, bioMerieux); and
- HIV-1 *in vitro* signal amplification, branched chain nucleic acid probe assay (bDNA) (VERSANT HIV-1 RNA 3.0 Assay, Bayer).

The lower limits of detection of the assays differ (<40 copies/mL for the Abbott Real Time HIV-1 test, <48 copies/mL for the AmpliPrep/TaqMan HIV-1 Test, <50 copies/mL for the Amplicor HIV-1 Monitor Test, <80 copies/mL for the NucliSens HIV-1 QT assay, and <75 copies/mL for the VERSANT assay). Use of ultrasensitive viral load assays to confirm that antiretroviral therapy is producing maximal suppression of viremia is recommended. Because of the variability of assay techniques and quantitative HIV RNA measurements between these assays, a single HIV RNA assay method should be used consistently for monitoring an individual patient, if possible.

The predominant virus subtype in the United States is B, which is the subtype for which all initial assays were targeted. Current kit configurations for all companies have been designed to detect and quantitate essentially all viral subtypes, with the exception of the uncommon O subtypes *[29-30]*. This is important for many regions of the world where non-B subtypes are predominant, as well as for the United States, where a small subset of individuals are infected with non-B viral subtypes *[31-33]*. Choice of HIV RNA assay, particularly for young children, may be influenced by the amount of blood required for the assay. The NucliSens assay requires the

least amount of blood (100 µL of plasma), followed by the RT PCR assays such as Amplicor HIV-1 Monitor (200 µL of plasma) and the VERSANT assays (1 mL of plasma).

Biologic variation in HIV RNA levels within one person is well documented. In adults, repeated measurement of HIV RNA levels using the same assay can vary by as much as threefold (0.5 $\log_{10}$) in either direction over the course of a day or on different days *[13, 21, 27]*. This biologic variation may be greater in infected infants and young children. In children with perinatally acquired HIV infection, RNA copy number slowly declines even without therapy during the first several years after birth, although it persists at higher levels than those observed in most infected adults *[16-18]*. This decline is most rapid during the first 12–24 months after birth, with an average decline of approximately 0.6 $\log_{10}$ per year; a slower decline continues until approximately 4–5 years of age (average decline of 0.3 $\log_{10}$ per year).

This inherent biologic variability must be considered when interpreting changes in RNA copy number in children. Thus, only changes after repeated testing greater than fivefold (0.7 $\log_{10}$) in infants younger than 2 years of age and greater than threefold (0.5 $\log_{10}$) in children 2 years of age and older should be considered reflective of a biologically and clinically substantial change.

No alteration in therapy should be made as a result of a change in HIV copy number unless the change is confirmed by a second measurement. Because of the complexities of HIV RNA testing and the age-related changes in HIV RNA in children, interpretation of HIV RNA levels for clinical decision making should be done by or in consultation with an expert in pediatric HIV infection.

Table 3. Likelihood of Developing AIDS or Death Within 12 Months, by Age and $CD4^+$ T-Cell Percentage or Log_{10} HIV-1 RNA Copy Number in HIV-Infected Children Receiving No Therapy or Zidovudine Monotherapy

	CD4 Percentage				Log_{10} HIV RNA Copy Number		
Age	**10%**	**20%**	**25%**	**30%**	**6.0**	**5.0**	**4.0**
Percent Mortality (95% Confidence Interval)							
6 Months	28.7	12 .4	8.5	6.4	9.7	4.1	2.7
1 Year	19.5	6.8	4.5	3.3	8.8	3.1	1.7
2 Years	11.7	3.1	2.0	1.5	8.2	2.5	1.1
5 Years	4.9	0.9	0.6	0.5	7.8	2.1	0.7
10 Years	2.1	0.3	0.2	0.2	7.7	2.0	0.6
Percent Developing AIDS (95% Confidence Interval)							
6 Months	51.4	31.2	24.9	20.5	23.7	13.6	10.9

Treatment Recommendations (Updated August 16, 2010)

GENERAL CONSIDERATIONS

Treatment of pediatric HIV infection in the United States has evolved since antiretroviral therapy began in the late 1980s. Prior to the availability of antiretroviral drugs for children, care focused on prevention and management of HIV-related complications and provision of palliative care. Initial studies of monotherapy in children in the early 1990s demonstrated significant clinical and immunologic benefit with treatment *[1-4]*; further research demonstrated that combination therapy (initially dual-NRTI treatment) led to better clinical, immunologic, and virologic outcomes than monotherapy *[5]*. Currently, highly active combination regimens including at least three drugs are recommended; such regimens have been associated with enhanced survival, reduction in opportunistic infections and other complications of HIV infection, improved growth and neurocognitive function, and improved quality of life in children *[6-10]*. In the United States and the United Kingdom, significant declines (81%–93%) in mortality have been reported in HIV-infected children between 1994 and 2006, concomitant with increased use of highly active combination regimens *[11-12]*; significant declines in HIV-related morbidity and hospitalizations in children have been observed in the United States and Europe over the same time period *[10, 12]*.

The increased survival of HIV-infected children is associated with challenges in selecting successive new antiretroviral drug regimens. Additionally, therapy is associated with short- and long-term toxicities, some of which are only now beginning to be recognized in children *[13-14]*.

Antiretroviral drug-resistant virus can develop in both multidrug experienced children and children who received initial regimens containing one or two drugs that incompletely suppressed viral replication. Additionally, drug resistance may be seen in antiretroviral-naïve children who have become infected with HIV despite maternal/infant antiretroviral prophylaxis *[15-16]*. Thus, decisions about when to start therapy and what drugs to choose in antiretroviral-naïve children and on how to best treat antiretroviral-experienced children remain complex. Whenever possible, decisions regarding the management of pediatric HIV infection should be directed by or made in consultation with a specialist in pediatric and adolescent HIV infection. Treatment of antiretroviral-naïve children (when and what to start), when to change therapy, and treatment of antiretroviral-experienced children will be discussed in separate sections of the guidelines.

A number of factors need to be considered in making decisions about initiating and changing antiretroviral therapy in children, including:

- severity of HIV disease and risk of disease progression, as determined by age, presence or history of HIV-related or AIDS-defining illnesses (see pediatric clinical staging system for HIV, **Table 6**) *[17-18]*, level of CD4 cell immunosuppression, and magnitude of HIV plasma viremia;
- availability of appropriate (and palatable) drug formulations and pharmacokinetic information on appropriate dosing in the child's age group;
- potency, complexity (e.g., dosing frequency, food and fluid requirements), and potential short- and long-term adverse effects of the antiretroviral regimen;
- effect of initial regimen choice on later therapeutic options;
- presence of comorbidity, such as tuberculosis, hepatitis B or C virus infection, or chronic renal or liver disease, that could affect drug choice;
- potential antiretroviral drug interactions with other prescribed, over-the-counter, or complementary/alternative medications taken by the child; and
- the ability of the caregiver and child to adhere to the regimen.

The following recommendations provide general guidance for decisions related to treatment of HIV-infected children, and flexibility should be exercised according to a child's individual circumstances. Guidelines for treatment of HIV-infected children are evolving as new data from clinical trials become available. Although

prospective, randomized, controlled clinical trials offer the best evidence for formulation of guidelines, most antiretroviral drugs are approved for use in pediatric patients based on efficacy data from clinical trials in adults, with supporting pharmacokinetic and safety data from Phase I/II trials in children. Additionally, efficacy has been defined in most adult trials based on surrogate marker data, as opposed to clinical endpoints. For the development of these guidelines, the Panel reviewed relevant clinical trials published in peer-reviewed journals or in abstract form, with attention to data from pediatric populations when available.

GOALS OF ANTIRETROVIRAL TREATMENT

Current antiretroviral therapies do not eradicate HIV infection due to the long half-life of latently infected CD4 cells *[19-21]*; some data suggest that the half-life of intracellular HIV proviral DNA is even longer in infected children than in adults (median 14 months vs. 5–10 months, respectively) *[21]*. Thus, based on currently available data, HIV causes a chronic infection likely requiring treatment for life once a child starts therapy. The goals of antiretroviral therapy for HIV-infected children include:

- reducing HIV-related mortality and morbidity;
- restoring and/or preserving immune function;
- maximally and durably suppressing viral replication;
- minimizing drug-related toxicity;
- maintaining normal physical growth and neurocognitive development; and
- improving quality of life.

Strategies to achieve these goals require complex balancing of sometimes competing considerations.

Use and selection of combination antiretroviral therapy: At present, the treatment of choice for HIV-infected children is at least three drugs, which include at least two classes of antiretroviral drugs. The Panel has recommended several preferred and alternative regimens (see **What Drugs to Start: Initial Combination Therapy for Antiretroviral-Naïve Children**). The most appropriate regimen for an individual child depends on multiple factors, including age of the child and availability of appropriate drug formulations; the potency, complexity, and toxicity of the regimen; the child and caregiver's ability to adhere to the regimen; the child's home situation; and the child's antiretroviral treatment history.

Drug sequencing and preservation of future treatment options: The choice of antiretroviral treatment regimens should include consideration of future treatment options, such as the presence of or potential for drug resistance. Multiple changes in antiretroviral drug regimens can rapidly exhaust treatment options and should be avoided unless required (e.g., severe toxicity or intolerance or significant clinical, immunologic, or virologic progression). Appropriate sequencing of drugs for use in initial and second-line therapy can preserve future treatment options and is another strategy to maximize long-term benefit from therapy. Currently, recommendations for initial therapy are to use two classes of drugs—two NRTIs combined with either an NNRTI or a PI—thereby sparing three classes of drugs for later use.

Maximizing adherence: As discussed in **Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents**, lack of adherence to prescribed regimens can lead to subtherapeutic levels of antiretroviral medications, which enhances the risk of the development of drug resistance and likelihood of virologic failure. Participation by the caregivers and child in the decision-making process is crucial. Issues related to adherence to therapy should be fully assessed, discussed, and addressed with the child's caregiver and the child (when age appropriate) before the decision to initiate therapy is made. Potential problems should be identified and resolved prior to starting therapy, even if this delays initiation of therapy. Additionally, frequent follow-up is important to provide assessment of virologic response to therapy, drug intolerance, viral resistance, and adherence. Finally, in patients who experience virologic failure, it is critical to fully assess adherence before making changes to the antiretroviral regimen.

Table 6. 1994 Revised Human Immunodeficiency Virus Pediatric Classification System: Clinical Categories*

Category N: Not Symptomatic

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A.

Category A: Mildly Symptomatic

Children with **two** or more of the following conditions but none of the conditions listed in Categories B and C:

- Lymphadenopathy (≥0.5 cm at more than two sites; bilateral = one site)
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Category B: Moderately Symptomatic

Children who have symptomatic conditions, other than those listed for Category A or Category C, that are attributed to HIV infection. Examples of conditions in Clinical Category B include, but are not limited to, the following:

- Anemia (<8 gm/dL), neutropenia (<1,000 cells/mm^3), or thrombocytopenia (<100,000 cells/mm^3) persisting ≥30 days
- Bacterial meningitis, pneumonia, or sepsis (single episode)
- Candidiasis, oropharyngeal (i.e., thrush) persisting for >2 months in children age >6 months
- Cardiomyopathy
- Cytomegalovirus infection with onset before age 1 month
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus (HSV) stomatitis, recurrent (i.e., more than two episodes within 1 year)
- HSV bronchitis, pneumonitis, or esophagitis with onset before age 1 month
- Herpes zoster (i.e., shingles) involving at least two distinct episodes or more than one dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia complex
- Nephropathy
- Nocardiosis
- Fever lasting >1 month
- Toxoplasmosis with onset before age 1 month
- Varicella, disseminated (i.e., complicated chickenpox)

Category C: Severely Symptomatic

Children who have any condition listed in the 1987 surveillance case definition for acquired immunodeficiency syndrome (below), with the exception of LIP (which is a Category B condition):

- Serious bacterial infections, multiple or recurrent (i.e., any combination of at least two culture-confirmed infections within a 2-year period), of the following types: septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal organ or body cavity (excluding otitis media, superficial skin or mucosal abscesses, and indwelling catheter-related infections)
- Candidiasis, esophageal or pulmonary (bronchi, trachea, lungs)
- Coccidioidomycosis, disseminated (at site other than or in addition to lungs or cervical or hilar lymph nodes)
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis or isosporiasis with diarrhea persisting >1 month
- Cytomegalovirus disease with onset of symptoms at age >1 month (at a site other than liver, spleen, or lymph nodes)
- Encephalopathy (at least one of the following progressive findings present for at least 2 months in the absence of a concurrent illness other than HIV infection that could explain the findings): a) failure to attain or loss of developmental milestones or loss of intellectual ability, verified by standard developmental scale or neuropsychological tests; b) impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy demonstrated by computerized tomography or magnetic resonance imaging (serial imaging is required for children <2 years of age); c) acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance
- Herpes simplex virus infection causing a mucocutaneous ulcer that persists for >1 month or bronchitis, pneumonitis, or esophagitis for any duration affecting a child >1 month of age
- Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes)
- Kaposi's sarcoma
- Lymphoma, primary, in brain
- Lymphoma, small, noncleaved cell (Burkitt's), or immunoblastic or large cell lymphoma of B-cell or unknown immunologic phenotype
- Mycobacterium tuberculosis, disseminated or extrapulmonary
- Mycobacterium, other species or unidentified species, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated (at site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Pneumocystis jiroveci* pneumonia
- Progressive multifocal leukoencephalopathy
- Salmonella (nontyphoid) septicemia, recurrent
- Toxoplasmosis of the brain with onset at >1 month of age
- Wasting syndrome in the absence of a concurrent illness other than HIV infection that could explain the following findings: a) persistent weight loss >10% of baseline; OR b) downward crossing of at least two of the following percentile lines on the weight-for-age chart (e.g., 95th, 75th, 50th, 25th, 5th) in a child ≥1 year of age; OR c) <5th percentile on weight-for-height chart on two consecutive measurements, ≥30 days apart **PLUS** 1) chronic diarrhea (i.e., ≥ two loose stools per day for >30 days), **OR** 2) documented fever (for ≥30 days, intermittent or constant)

When to Initiate Therapy in Antiretroviral-Naïve Children (Updated August 16, 2010)

The choice of whether to start therapy early, while an individual is still asymptomatic, versus delaying therapy until clinical or immunologic deterioration occurs continues to generate considerable controversy among HIV experts. Some experts favor starting aggressive therapy in the early stages of HIV infection in the hope that early antiretroviral intervention will control viral replication prior to the onset of rapid genetic mutation and evolution into multiple quasi-species. This could result in a lower viral set point, fewer mutant viral strains, and potentially less drug resistance. Early therapy would slow immune system destruction and preserve immune function, preventing clinical disease progression. On the other hand, delaying therapy until later in the course of HIV infection, when clinical or immunologic symptoms appear, may result in reduced evolution of drug-resistant virus due to a lack of drug selection pressure, greater adherence to the therapeutic regimen when the patient is symptomatic rather than asymptomatic, and reduced or delayed adverse effects of antiretroviral therapy.

Recommendations for when to initiate therapy have generally been more aggressive in children than adults because HIV infection is primarily transmitted from mother to child, thereby allowing identification of the timing of infection in children; HIV disease progression in children is more rapid than in adults; and laboratory parameters are less predictive of risk of disease progression in children, particularly for young infants. As discussed in **Laboratory Monitoring of Pediatric HIV Infection**, CD4 count and HIV RNA values vary considerably by age in children, and both markers are poorly predictive of disease progression and mortality in children younger than 12 months. Hence, recommendations for when to start therapy differ by age of the child. As discussed earlier, in the HIV Pediatric Prognostic Markers Collaborative Study meta-analysis, CD4 percentage and HIV RNA levels were both independently predictive of the risk of clinical progression or death in children older than 12 months, although CD4 percentage was a stronger predictor of risk than HIV RNA levels *[1]*. Based on data showing that surrogate marker-based risk of progression varies considerably by age but that CD4 count-associated risk of progression in children age 5 years or older is similar to young adults, the Panel has moved to recommendations for three age bands for initiation of treatment: infants younger than age 12 months, children age 1 to <5 years, and children and adolescents age ≥5 years.

ANTIRETROVIRAL-NAÏVE HIV-INFECTED INFANTS YOUNGER THAN AGE 12 MONTHS

Panel's Recommendations (Table 7):

- ***Initiation of antiretroviral therapy is recommended for infants age <12 months, regardless of clinical status, CD4 percentage, or viral load (AI).***
- ***Issues associated with adherence must be fully assessed and discussed with the HIV-infected infant's caregivers before therapy is initiated (AIII).***

Data from the South African CHER Trial (Children with HIV Early Antiretroviral Therapy) demonstrated that initiation of triple-drug antiretroviral therapy prior to 12 weeks of age in asymptomatic perinatally infected children with normal CD4 percentage (CD4 >25%), compared with waiting to start treatment until the child met clinical or immune criteria, resulted in a 75% reduction in early mortality*[2]*. Most of the deaths in the children in the delayed arm occurred in the first 6 months after study entry. Because the risk of rapid progression is so high in young infants and based on the data from the CHER study, the Panel recommends initiation of therapy for all infants age <12 months regardless of clinical status, CD4 percentage, or viral load (**Table 7**). It is critical that issues associated with adherence are fully assessed and discussed with the HIV-infected infant's caregivers and addressed before therapy is initiated.

The risk of disease progression is inversely correlated with the age of the child, with the youngest children at greatest risk of rapid disease progression. Progression to moderate or severe immune suppression is also frequent in infected infants; by 12 months of age, approximately 50% of children develop moderate immune suppression and 20% develop severe immune suppression *[3]*. In the HIV Pediatric Prognostic Markers Collaborative Study meta-analysis, the 1-year risk of AIDS or death was substantially higher in younger than in older children at any given level of CD4 percentage, particularly for infants age <12 months *[4]*. Unfortunately, although the risk of progression is greatest in the first year of life, the ability to differentiate children at risk of rapid versus slower disease progression by clinical and laboratory parameters is also most limited in young infants. No specific "at-risk" viral or immunologic threshold can be easily identified, and progression of HIV disease and opportunistic infections can occur in young infants with normal CD4 counts *[4]*.

Identification of HIV infection during the first few months of life permits clinicians to initiate antiretroviral therapy during the initial phases of primary infection. Data from a number of observational studies in the United States and Europe suggest that infants who receive early treatment are less likely to progress to AIDS or death than those who started therapy later. Analyses from a prospective study of 360 HIV-infected children in the United States (Perinatal AIDS Collaborative Transmission Study [PACTS]) showed that infants who received early treatment (prior to age 2 years, with nearly half starting in the first year of life) were significantly less likely to progress to AIDS or death compared with those who received no therapy, adjusting for year of birth and maternal disease factors *[5]*. In the European Infant Collaboration Group, starting antiretroviral therapy before the age of 3 months was associated with a significant reduction in progression to AIDS or death compared with deferring therapy *[6]*. In an analysis from the European Collaborative Study, HIV-infected children who initiated potent therapy before age 5 months were more likely to achieve CD4 recovery (defined as 20% increase in CD4 *z* score) than children initiating therapy at older ages *[7]*.

Several small studies have demonstrated that despite the very high levels of viral replication in perinatally infected infants, early initiation of treatment can result in durable viral suppression and normalization of immunologic responses to non-HIV antigens in some infants. In infants with sustained control of plasma viremia, there has also been lack of detection of extra-chromosomal replication intermediates, suggesting near-complete control of viral replication. Some of these infants have become HIV seronegative and have lost HIV-specific immune responses. However, therapy is not curative; proviral HIV-1 DNA continues to be detectable in peripheral blood lymphocytes and viral replication resumes if therapy is discontinued *[8-9]*.

There are, however, potential problems with treatment of asymptomatic infants. Virologic suppression may take longer in young children (given their higher viral load at the time of initiation of therapy) than in older children or adults *[10]*, and the rates of virologic failure with therapy started early in life may be higher than when started later *[11]*. Incomplete viral suppression can lead to the development of drug resistance and compromise future treatment options *[12]*. Possible reasons for the poor response in infants include very high viral loads in young infants, inadequate antiretroviral drug levels, and poor adherence due to the difficulties in administering complex regimens to infants. However, with currently available drug regimens, rates of viral suppression of 70%–80% have been reported in HIV-infected infants initiating therapy at age <12 months *[13-15]*. In a 5-year follow-up study of 40 HIV-infected children who initiated treatment at age <6 months, 98% had CD4 >25% and 78% had undetectable viral load with median follow-up of 5.96 years *[13]*.

Information on appropriate drug dosing in infants younger than age 3–6 months is limited. Hepatic and renal functions are immature in the newborn undergoing rapid maturational changes during the first few months of life which can result in substantial differences in antiretroviral dose requirements between young infants and older children. When drug concentrations are subtherapeutic, either because of inadequate dosing, poor absorption, or incomplete adherence, antiretroviral drug resistance can develop rapidly, particularly in the setting of high levels of viral replication in young infants. It is particularly critical to discuss fully the importance of treatment adherence with the caregivers and to identify and resolve potential problems prior to initiation of therapy, even if this delays starting treatment. Frequent follow-up and continued assessment and support of adherence are especially important in the treatment of young infants (see **Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents**).

Finally, the possibility of toxicities—such as lipodystrophy, dyslipidemia, glucose intolerance, osteopenia, and mitochondrial dysfunction—with prolonged therapy is a concern *[16]*. Concerns about toxicities are particularly relevant because life-long administration of therapy may be necessary. Whether it might be possible to stop therapy begun in early infancy after a defined period of treatment (e.g., 1–2 years) that protected the child during the period of greatest risk of HIV disease progression and mortality, and then restart therapy when the child meets standard age-related criteria, is under assessment in clinical trials in South Africa and Kenya.

ANTIRETROVIRAL-NAÏVE HIV-INFECTED CHILDREN AGE 1 YEAR OR OLDER

Panel's Recommendations (Table 7):

- ***Initiation of antiretroviral therapy is recommended for children age ≥1 year with AIDS or significant symptoms (Clinical Category C or most Clinical Category B conditions), regardless of CD4 percentage/count or plasma HIV RNA level (AI*).***
- ***Initiation of antiretroviral therapy is also recommended for children age ≥1 year who have met the age-related CD4 threshold for initiating treatment (CD4 <25% for children age 1 to <5 years (AII) and <350 cells/mm^3 for children age ≥5 years (AI*), regardless of symptoms or plasma HIV RNA level).***
- ***Initiation of antiretroviral therapy is also recommended for children age ≥1 year who are asymptomatic or have mild symptoms (Clinical Categories N and A or the following Clinical Category B conditions: single episode of serious bacterial infection or lymphoid interstitial pneumonitis) and have CD4 ≥25% for children age 1 to <5 years or ≥350 cells/mm^3 for children age ≥5 years and have plasma HIV RNA ≥100,000 copies/mL (BII).***
- ***Initiation of antiretroviral therapy may be considered or deferred for children age ≥1 year who are asymptomatic or have mild symptoms and who have CD4 ≥25% for children age 1 to <5 years and ≥350 cells/mm^3 for children age ≥5 years and have plasma HIV RNA <100,000 copies/mL (CIII).***

The risk of disease progression slows in children age ≥1 year. It is clear that children with clinical AIDS or significant symptoms (Clinical Category C or B—**Table 6**) *[17]* are at high risk of disease progression and death; treatment is recommended by the Panel for all such children, regardless of immunologic or virologic status. However, children age ≥1 year with mild clinical symptoms (Clinical Category A) or who are asymptomatic (Clinical Category N) are at lower risk of disease progression than those with more severe clinical symptoms *[18]*. It should also be noted that some Clinical Category B conditions—a single episode of serious bacterial infection or lymphoid interstitial pneumonitis—are less prognostic of the risk of disease progression. Consideration of CD4 count and viral load may be useful in determining the need for therapy in children with these conditions.

In adults, considerations related to initiation of antiretroviral therapy are based primarily on risk of disease progression as determined by baseline CD4 count *[19]*. In adults, both clinical trial and observational data support initiation of treatment in individuals with CD4 count <350 cells/mm^3. In HIV-infected adults in Haiti, a randomized clinical trial found significant reductions in mortality and morbidity with initiation of treatment when CD4 count fell to <350 cells/mm^3 compared with deferring treatment until CD4 count fell to <200 cell/mm^3*[20]*. In observational data in adults, a collaborative analysis of data from 12 adult cohorts in North America and Europe on 20,379 adults starting treatment between 1995 and 2003, the risk of AIDS or death was significantly less in those who started treatment with CD4 count of 200–350 cells/mm^3 compared with those who started at <200 cells/mm^3 *[21]*.

There are no randomized trial data to address the comparative efficacy of starting versus deferring treatment at higher CD4 thresholds in HIV-infected adults or children. Two observational studies in adults, the ART Cohort Collaboration (ART-CC) and NA-Accord, suggest a higher rate of progression to AIDS or death in patients deferring treatment until CD4 count <350 cells/mm^3 compared with starting when CD4 count was 351 to 450–500 cells/mm^3 *[22-23]*. However, although the relative risk was increased, the overall number of events was small. The NA-Accord study demonstrated a benefit of starting treatment when CD4 count was >500 cell/mm^3

compared with starting when CD4 fell below this threshold *[22]*; however the ART-CC cohort found no additional benefit for patients starting antiretroviral therapy with CD4 counts greater than 450 cells/mm^3 *[23]*. The HHS Adult Antiretroviral Guidelines Panel was split on recommendations regarding starting therapy in HIV-infected adults with CD4 count 350–500 cells/mm^3 (moderate to strong recommendation) and >500 cells/mm^3 (moderate recommendation to optional) *[19]*.

In children, the prognostic significance of a specific CD4 percentage or count varies with age *[4, 24]*. Data from pediatric studies also suggest the immune response to treatment in children is better when treatment is initiated at higher CD4 percentage/count levels *[11, 25]*. In data from the HIV Pediatric Prognostic Markers Collaborative Study meta-analysis, derived from 3,941 children with 7,297 child-years of follow-up, the risk of mortality or progression to AIDS per 100 child-years is significantly higher for any given CD4 count among children age 1–4 years than among children age ≥5 years (**Tables 3–4** and **Figures 1–2**). Data from the HIV Pediatric Prognostic Markers Collaborative Study suggest that absolute CD4 cell count is a useful prognostic marker for disease progression in children age ≥5 years, in whom the estimated risk of disease progression increases when the count falls below 350 cells/mm^3, similar to data in adults (**Table 4**) *[1, 4]*. For children age 1 to <5 years, a similar increase in risk of AIDS or death is seen when CD4 percentage drops below 25% (**Table 3**).

The level of plasma HIV RNA may provide useful information in terms of risk of progression, although its prognostic significance is weaker than CD4 count *[4]*. Several studies have shown that older children with HIV RNA levels ≥100,000 copies/mL are at high risk of mortality *[26-27]*; similar data have been reported in adults *[28]*. Similarly, in the HIV Pediatric Prognostic Markers Collaborative Study meta-analysis, the 1-year risk of progression to AIDS or death rose sharply for children age >1 year when HIV RNA levels were ≥100,000 copies/mL (**Table 3** and **Figures 4–5**) *[4]*. For example, the estimated 1-year risk of death was 2–3 times higher in children with plasma HIV RNA of 100,000 copies/mL compared with 10,000 copies/mL and 8–10 times higher if plasma HIV RNA was >1,000,000 copies/mL.

Based on these data, the Panel has the following recommendations for treatment of children age 1 to <5 years. Initiation of antiretroviral therapy is recommended for children age 1 to <5 years who have AIDS or significant HIV-related symptoms (CDC Clinical Categories C and B, except for the following Category B conditions: single episode of serious bacterial infection or lymphoid interstitial pneumonitis [**Table 6**]), regardless of CD4 percentage/count or HIV RNA level. Additionally, treatment is recommended for children in this age group if they have a CD4 percentage <25%, regardless of clinical symptoms or HIV RNA level. Treatment is also recommended for children who are asymptomatic or have mild symptoms (Clinical Categories N and A, or Clinical Category B disease due to a single episode of serious bacterial infection or lymphoid interstitial pneumonitis [**Table 6**]) with CD4 percentage ≥25% if plasma HIV RNA is >100,000 copies/mL. Antiretroviral therapy may be considered or deferred in asymptomatic children age 1 to <5 years who have CD4 ≥25% and who also have plasma HIV RNA levels <100,000 copies/mL.

For children who are age 5 years or older, initiation of antiretroviral therapy is recommended if they have AIDS or significant HIV-related symptoms (CDC Clinical Categories C and B, except for the following Category B conditions: single episode of serious bacterial infection or lymphoid interstitial pneumonitis [**Table 6**]), regardless of CD4 percentage/count or HIV RNA level. Additionally, treatment is recommended for children in this age group if they have CD4 <350 cells/mm^3, regardless of clinical symptoms or HIV RNA level. Treatment is also recommended for children who are asymptomatic or have mild symptoms (Clinical Categories N and A, or Clinical Category B disease due to a single episode of serious bacterial infection or lymphoid interstitial pneumonitis [**Table 6**]) with CD4 ≥350 cells/mm^3 if HIV RNA is >100,000 copies/mL. Antiretroviral therapy may be considered or deferred for asymptomatic or mildly symptomatic children age ≥5 years who have CD4 ≥350 cells/mm^3 and who also have plasma HIV RNA levels <100,000 copies/mL.

If therapy is deferred, the health care provider should closely monitor virologic, immunologic, and clinical status (see **Laboratory Monitoring of Pediatric HIV Infection**). Factors to consider in deciding when to initiate therapy in children in whom treatment was deferred include:

- Increasing HIV RNA levels (e.g., HIV RNA levels approaching 100,000 copies/mL);
- Rapidly declining CD4 count or percentage to values approaching the age-related threshold for consideration of therapy;
- Development of clinical symptoms; and
- The ability of caregiver and child to adhere to the prescribed regimen.

Table 7. Indications for Initiation of Antiretroviral Therapy in HIV-Infected Children

This table provides general guidance rather than absolute recommendations for an individual patient. Factors to be considered in decisions about initiation of therapy include the risk of disease progression as determined by CD4 percentage or count and plasma HIV RNA copy number, the potential benefits and risks of therapy, and the ability of the caregiver to adhere to administration of the therapeutic regimen. Issues associated with adherence should be fully assessed, discussed, and addressed with the child, if age appropriate, and the caregiver before the decision to initiate therapy is made.

Age	Criteria	Recommendation
<12 months	• Regardless of clinical symptoms, immune status, or viral load	*Treat (AI)*
1–<5 years	• AIDS or significant HIV-related symptoms[1]	*Treat (AI*)*
	• CD4 <25%, regardless of symptoms or HIV RNA level	*Treat (AII)*
	• Asymptomatic or mild symptoms[2] *and* o CD4 ≥25% *and* o HIV RNA ≥100,000 copies/mL	*Treat (BII)*
	• Asymptomatic or mild symptoms[2] *and* o CD4 ≥25% *and* o HIV RNA <100,000 copies/mL	*Consider or Defer*[3] *(CIII)*
≥5 years	• AIDS or significant HIV-related symptoms[1]	*Treat (AI*)*
	• CD4 <350 cells/mm^3	*Treat (AI*)*
	• Asymptomatic or mild symptoms[2] *and* o CD4 ≥350 cells/mm^3 *and* o HIV RNA ≥100,000 copies/mL	*Treat (BII)*
	• Asymptomatic or mild symptoms[2] *and* o CD4 ≥350 cells/mm^3 *and* o HIV RNA <100,000 copies/mL	*Consider or Defer*[3] *(CIII)*

[1] CDC Clinical Categories C and B (except for the following Category B conditions: single episode of serious bacterial infection or lymphoid interstitial pneumonitis)

[2] CDC Clinical Category A or N or the following Category B conditions: single episode of serious bacterial infection or lymphoid interstitial pneumonitis

[3] Clinical and laboratory data should be re-evaluated every 3 to 4 months.

What Drugs to Start: Initial Combination Therapy for Antiretroviral-Naïve Children

(Updated August 16, 2010)

Panel's Recommendations:

- ***Antiretroviral drugs initiated for chemoprophylaxis of maternal-child HIV transmission should be discontinued in infants who are identified as HIV infected (AI) and treatment initiated with combination therapy as described below.***
- ***Antiretroviral drug-resistance testing is recommended prior to initiation of therapy in all treatment-naïve children (AII infants; AIII children).***
- ***The goal of therapy in treatment-naïve children is to reduce plasma HIV RNA levels to below the limits of quantitation on ultrasensitive assays and to preserve or normalize immune status (AI).***
- ***Combination therapy with at least three drugs, including either a non-nucleoside reverse transcriptase inhibitor or protease inhibitor plus a dual nucleoside analogue reverse transcriptase inhibitor backbone, is recommended for initial treatment of HIV-infected children (AI).***

GENERAL CONSIDERATIONS

As of August 2010, 22 antiretroviral drugs are approved for use in HIV-infected adults and adolescents; 17 of these have an approved pediatric treatment indication and 15 are available as a pediatric formulation or capsule size. These drugs fall into several major classes: nucleoside analogue or nucleotide analogue reverse transcriptase inhibitors (NRTIs, NtRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), entry inhibitors (including fusion inhibitors and CCR5 antagonists), and integrase inhibitors. Brief information on drug formulation, pediatric dosing, and toxicity for the individual drugs and detailed information on drug interactions can be found in **Appendix B: Pediatric Antiretroviral Drug Information**. It is likely that new drugs and drug combinations that demonstrate sustainable viral load suppression and acceptable toxicity and dosing profiles will become available over time, which will increase treatment options for children.

Combination antiretroviral therapy with at least three drugs from at least two classes of drugs is recommended for initial treatment of infected infants, children, and adolescents because it provides the best opportunity to preserve immune function and delay disease progression *[1-4]*. The goal of antiretroviral therapy is to maximally suppress viral replication, preferably to undetectable levels, for as long as possible while preserving and/or restoring immune function and minimizing drug toxicity. Combination therapy slows disease progression and improves survival, results in a greater and more sustained virologic and immunologic response, and delays development of virus mutations that confer resistance to the drugs being used *[3-5]*.

Because antiretroviral therapy will need to be administered lifelong, considerations related to the choice of initial antiretroviral regimen should also include an understanding of barriers to adherence, including the complexity of schedules and food requirements for different regimens; differing formulations; palatability problems; and potential limitations in subsequent treatment options should resistance develop.

Monotherapy and two-drug therapy with the currently available antiretroviral drugs are not recommended to treat HIV infection *[1, 6]*. Use of zidovudine as a single agent is appropriate only when used in infants of indeterminate HIV status during the first 6 weeks of life to prevent perinatal HIV transmission. Infants confirmed as HIV infected while receiving chemoprophylaxis should have prophylactic antiretroviral drugs discontinued and treatment initiated with a combination regimen of at least 3 drugs (which may include zidovudine as part of the regimen if sensitive). The choice of regimen should be based on results from

antiretroviral drug resistance testing. Treatment should only be initiated following assessment and counseling of the caregivers regarding adherence to therapy *[1, 6]*.

Antiretroviral drug-resistance testing is recommended prior to the initiation of therapy in all treatment-naïve children. Treatment-naïve children with perinatal HIV infection can acquire drug-resistant virus from their mothers (because the mothers were initially infected with drug-resistant virus or acquired drug resistance during treatment or during use of antiretroviral drugs for prevention of mother-to-child transmission of HIV [PMTCT]), or the infant can develop resistance during the period of infant antiretroviral prophylaxis prior to diagnosis of HIV infection. Drug-resistant virus has been identified in 6%–16% of antiretroviral-naïve adults and 18% of behaviorally infected adolescents with recent infection in United States and Europe *[7-11]*. Data from children are limited. In a study in New York State, genotypic drug resistance was identified in 12% of 91 HIV-infected infants born from 1998 to 1999 and 19% of 42 infants born from 2000 to 2001 *[12-13];* detection of resistance in the infants was not signficantly associated with a history of maternal and infant antiretroviral prophylaxis. Similarly, following initiation of treatment, 24% of 21 infants (median age 9.7 weeks) were found to have mutations associated with drug resistance, most of which were not associated with maternal/infant prophylaxis regimens; resistant virus was found to be persistently archived in the resting CD4 cell reservoir *[14]*. Thus, the prevalence of infants infected with antiretroviral drug-resistant virus may be increasing and may not necessarily be predicted by the drug prophylaxis regimen received by the mother. In a recent trial, pretreatment detection of nevirapine resistance mutations was associated with a significantly higher rate of virologic failure of a nevirapine-based regimen among infants exposed to peripartum nevirapine used as maternal-infant prophylaxis *[15]*. For antiretroviral-naïve children beyond infancy, limited available data do not demonstrate that resistance testing prior to initiation of therapy correlates with greater success of initial antiretroviral therapy *[16]*. Nevertheless, the prevalence of resistance in HIV-infected children is sufficiently high that, based on expert opinion, the Panel recommends resistance testing prior to initiation of therapy in all treatment-naïve children and use of resistance testing results to refine selection of drugs for inititial combination therapy, similar to recommendations for HIV-infected adults *[17]*. Infants exposed to peripartum nevirapine as part of maternal-infant prophylaxis should not use nevirapine-based regimens for initial combination therapy, even if baseline resistance testing with standard commercial assays fails to demonstrate mutations associated with nevirapine resistance because the presence of minor resistance variants may be associated with virologic failure of NNRTI-based therapy *[18]*.

REGIMENS RECOMMENDED FOR INITIAL THERAPY OF ANTIRETROVIRAL-NAÏVE CHILDREN (TABLES 8 AND 9)

Criteria Used for Recommendations

There are few randomized, Phase III clinical trials of combination antiretroviral therapy among pediatric patients that provide direct comparison of different treatment regimens; most pediatric drug data come from Phase I/II safety and pharmacokinetic trials and nonrandomized, open-label studies. The Panel reviews both pediatric and adult clinical trial data published in peer-reviewed journals, data prepared by manufacturers for FDA review, and data presented in abstract format at major scientific meetings. In general, even in studies in adults, assessment of efficacy and potency is primarily based on surrogate marker endpoints, such as CD4 cell count and HIV RNA levels. Recommendations on the optimal initial therapy for children are continually being modified as new data become available, new therapies or drug formulations are developed, and late toxicities become recognized.

Criteria used by the Panel for recommending specific drugs or regimens include:

- Data demonstrating durable viral suppression, immunologic improvement, and clinical improvement (when such data are available) with the regimen, preferably in children as well as adults;
- The extent of pediatric experience with the particular drug or regimen;
- Incidence and types of short- and long-term drug toxicity with the regimen, with special attention to toxicity reported in children;

- Availability and acceptability of formulations appropriate for pediatric use, including palatability, ease of preparation (e.g., powders), volume of syrups, and pill size and number;
- Dosing frequency and food and fluid requirements; and
- Potential for drug interactions.

Drugs or drug combinations are classified in one of several categories as follows:

- ***Preferred:*** Drugs or drug combinations are designated as preferred for use in treatment-naïve children when clinical trial data in children or, more often, in adults have demonstrated optimal efficacy and durability with acceptable toxicity and ease of use, and studies have been performed to demonstrate safety and surrogate marker efficacy in children; additional considerations are listed above.
- ***Alternative:*** Drugs or drug combinations are designated as alternatives for initial therapy when clinical trial data in children or adults show efficacy but there are disadvantages compared with preferred regimens in terms of more limited experience in children; the extent of antiviral efficacy or durability is less well defined in children or less than a preferred regimen in adults; there are specific toxicity concerns; or there are dosing, formulation, administration, or interaction issues for that drug or regimen.
- ***Use in Special Circumstances:*** Some drugs or drug combinations are recommended for use as initial therapy only in special circumstances, when preferred or alternative drugs cannot be used.
- ***Not Recommended:*** A list of drugs and drug combinations that are not recommended for initial therapy in children is shown in **Table 9**. These drugs and drug combinations are not recommended either because of inferior virologic response, potential serious safety concerns (including potentially overlapping toxicities), or pharmacologic antagonism.
- ***Insufficient Data to Recommend:*** For a number of drugs and drug combinations approved for use in adults, pharmacokinetic or safety data in children are not available or are too limited to make recommendation on use of the drugs as initial therapy in children. Some of these drugs and drug combinations may be appropriate for consideration in the management of the treatment-experienced child, even though they are not recommended for initial therapy in children (see **Antiretroviral Treatment Failure in Infants, Children, and Adolescents**).

The most extensive clinical trial data on initial therapy regimens in adults and children are available for three types of regimens based on drug class: NNRTI based (two NRTIs plus an NNRTI); PI based (two NRTIs plus a PI); and NRTI only (three NRTI drugs). NNRTI- or PI-based regimens are preferred for initial therapy; decisions about which type of regimen to choose should be individualized based on patient characterisitics. Each class-based regimen has advantages and disadvantages that are delineated in more detail in the sections that follow and in **Tables 10–13**.

Choice of NNRTI- Versus PI-Based Initial Regimens for Children Younger Than 3 Years of Age

One special scenario is the choice of initial therapy for children < 3 years of age. The only preferred regimens for children < 3 years are coformulated lopinavir/ritonavir-based therapy and nevirapine-based therapy. Infants exposed to nevirapine in the peripertum period as part of PMTCT strategy should not be treated with nevirapine-based combination therapy because of the established higher risk of treatment failure due to nevirapine resistance *[15, 19]*, and lopinavir/ritonavir-based combination therapy would be the only recommended, preferred initial regimen. In addition, many experts in the United States recommend coformulated lopinavir/ritonavir-based therapy over nevirapine-based therapy even in the absence of peripartum nevirapine exposure because of concern about greater potential hepatotoxicity, lower barrier to resistance, and higher rate of virologic failure with nevirapine compared with lopinavir/ritonavir *[20-22]*. However, evidence is lacking for increased toxicity of nevirapine compared with lopinavir/ritonavir in infants *[15]* and some experts prefer nevirapine-based therapy because of the poor palatability of liquid lopinavir/ritonavir. Ongoing studies are expected to provide clearer evidence about the relative superiority of NNRTI- versus PI-based regimens in infants and children.

PREFERRED REGIMENS FOR INITIAL THERAPY OF CHILDREN (TABLE 8)

NNRTI-Based Regimens (one NNRTI + two-NRTI backbone)

Panel's Recommendations:

- ***Preferred NNRTI:***
  - ***Nevirapine in combination with two NRTIs for children age <3 years who have not been exposed to nevirapine as part of maternal-infant prophylaxis or who require a liquid formulation (BI*).***
  - ***Efavirenz in combination with two NRTIs for children age ≥3 years (AI*).***
- ***Alternative NNRTI:***
  - ***Nevirapine in combination with two NRTIs (for children age ≥3 years) (BI*).***

The Panel does not recommend the following NNRTIs as part of initial therapy in children:

- ***Etravirine is not recommended due to lack of pediatric formulation, pediatric pharmacokinetic data, efficacy or safety data in children, and lack of data in antiretroviral-naïve patients (BIII).***
- ***Nevirapine is not recommended for infants exposed to nevirapine as part of maternal-infant prophylaxis (AI).***
- ***Nevirapine is not recommended for postpubertal girls with CD4 count >250/mm^3 (AII*).***
- ***Efavirenz is not recommended for sexually active female adolescents when reliable contraception cannot be assured (BIII).***
- ***Efavirenz is not recommended for children <3 years of age (BIII).***

Summary: NNRTI-Based Regimens

Nevirapine and efavirenz both have an approved pediatric indication. Nevirapine is available in a liquid formulation, but efavirenz is not available in a liquid formulation in the United States. Advantages and disadvantages of different NNRTI drugs are delineated in **Table 11**. Use of NNRTIs as initial therapy preserves the PI class for future use, and less dyslipidemia and fat maldistribution have been reported with the NNRTI class than with the PI class. Additionally, there is generally a lower pill burden with these agents when compared with PI-based regimens for children taking solid formulations. The major disadvantages of the current NNRTI drugs approved for use in children arethat a single viral mutation can confer drug resistance, and cross resistance develops between nevirapine and efavirenz. In infants exposed to nevirapine as part of PMTCT, higher virologic failure rates have been demonstrated with nevirapine-based regimens compared with lopinavir/ritonavir-based regimens *[15]*. Rare but serious and potentially life-threatening skin and hepatic toxicity can occur with all drugs in this class, but is most frequent with nevirapine, at least in HIV-infected adults. NNRTI drugs have the potential for drug interactions due to metabolism via hepatic enzymes; however, these are less frequent than those of boosted PI regimens.

Efavirenz, in combination with two NRTIs, is the preferred NNRTI for initial therapy of children age ≥3 years based on clinical trial experience in children and because higher rates of toxicity have been observed with nevirapine in clinical trials in adults. Results of studies comparing virologic response to nevirapine- versus efavirenz-based regimens in adults are conflicting, and no randomized studies have been done in children. Because nevirapine therapy is associated with the rare occurrence of significant hypersensitivity reactions, including Stevens-Johnson syndrome and rare but potentially life-threatening hepatitis *[23-24]*, nevirapine is recommended as an alternative, rather than a preferred, NNRTI for initial treatment of antiretroviral-naïve children age ≥3 years. In infants and children <3 years who require a liquid NNRTI-based regimen, nevirapine is preferred.

Efavirenz as preferred NNRTI: In clinical trials in HIV-infected adults, a PI-sparing regimen of efavirenz in combination with zidovudine and lamivudine was associated with an excellent virologic response, with 70% of treated individuals having plasma HIV RNA <400 copies/mL at 48 weeks *[25]*. In randomized controlled trials in treatment-naïve adults, superior or similar virologic activity has been demonstrated in efavirenz-treated

patients compared with individuals receiving PI- or triple NRTI-based regimens *[26-29]*. Clinical trials in adults are conflicting in terms of comparative efficacy of efavirenz and nevirapine (see discussion below) *[30-34]*. No comparative trials have been conducted in children. However, an analysis of children and adults starting first-line antiretroviral therapy in Uganda has demonstrated the superiority of an efavirenz-based regimen compared with a nevirapine-based regimen in 222 children and adolescents (mean age, 9.2 years) *[22]*.

Efavirenz has been studied in HIV-infected children in combination with two NRTIs or with an NRTI and a PI *[35-41]*. Results are comparable to those seen in adults. At this time, no pediatric formulation of efavirenz is available in the United States. The appropriate dose of efavirenz for children age <3 years has not been determined, and it is therefore not recommended for this age group. Some clinicians would recommend opening the capsules and adding the contents to food or liquid for children age ≥3 years who cannot swallow pills; however, there are no pharmacokinetic data on use in this fashion and it is not recommended.

The major limitations of efavirenz are central nervous system side effects in both children and adults; reported side effects include fatigue, poor sleeping patterns, vivid dreams, poor concentration, agitation, depression, and suicidal ideation. Although in most patients this toxicity is transient, in some patients the symptoms may persist or occur months after first initiating efavirenz. In several studies, the incidence of such side effects was correlated with efavirenz plasma concentrations and occurred more frequently in adult patients with higher levels of drug *[42-45]*. In patients with pre-existing psychiatric conditions, efavirenz should be used cautiously for initial therapy. Rash may also occur with efavirenz treatment; it is generally mild and transient but appears to be more common in children than adults *[39, 41]*. Additionally, efavirenz is potentially teratogenic to the fetus if taken by a pregnant woman during the first trimester of pregnancy (see **Appendix B: Pediatric Antiretroviral Drug Information** for detailed information). Unless adequate contraception can be ensured, it is not recommended for initial therapy in adolescent females who are sexually active and may become pregnant.

Nevirapine as alternative NNRTI: Nevirapine has extensive clinical and safety experience in HIV-infected children and has shown antiretroviral efficacy in a number of different combination regimens (see **Appendix B: Pediatric Antiretroviral Drug Information** for detailed information) *[46]*. Nevirapine has been studied in HIV-infected children in combination with two NRTIs or with an NRTI and a PI *[47-49]*.

In a large adult trial (2NN trial), although virologic efficacy was comparable between nevirapine and efavirenz (plasma HIV RNA <50 copies/mL at 48 weeks in 56% of those receiving nevirapine vs. 62% of those receiving efavirenz), serious hepatic toxicity was more frequent in the nevirapine arm than the efavirenz arm (hepatic laboratory toxicity in 8%–14% of those on nevirapine, compared with 5% on efavirenz) *[34]*. Other studies in adults have indicated potentially increased risk of hepatic toxicity with nevirapine-based compared with efavirenz-based regimens *[50]*. Additionally, data in adults indicate that symptomatic hepatic toxicity is more frequent in individuals with higher CD4 count and in women, particularly women with CD4 >250 cells/mm^3 and men with CD4 >400 cells/mm^3. This may be less of an issue for prepubertal children. In the published literature, hepatic toxicity appears to be less frequent in children receiving chronic nevirapine therapy than in adults *[48-49, 51]*. In an FDA review of 783 HIV-infected pediatric patients, there was only 1 case of hepatitis, which was reported in a 17-year-old; there was no evidence of a serious hepatic event associated with nevirapine use in any child prior to adolescence *[51]*. In contrast, skin and hypersensitivity reactions have been reported in children *[52]*. The safety of substituting efavirenz for nevirapine in patients who have experienced nevirapine-associated hepatic toxicity is unknown; efavirenz use in this situation has been well tolerated in the very limited number of patients in whom it has been reported but should be attempted with caution *[53]*.

Because of the higher potential for toxicity and possibly an increased risk of virologic failure, nevirapine-based regimens are considered as alternative rather than preferred NNRTI in children age ≥3 years. Because appropriate dosing information for nevirapine in young children is available and there is a liquid formulation, nevirapine is the preferred NNRTI for children who are age <3 years or those who require a liquid formulation. Nevirapine should not be used in infants exposed to nevirapine as part of PMTCT *[15]*. Similar to recommendations in adults, nevirapine also should not be used in postpubertal adolescent girls with CD4

count >250/mm^3 due to the increased risk of symptomatic hepatic toxicity, unless the benefit clearly outweighs the risk *[24]*.

PI-Based Regimens (PIs [boosted or unboosted] + two- NRTI backbone)

Panel's Recommendations:

- ***Preferred PI:***
  - ***Lopinavir/ritonavir in combination with two NRTIs (AI*).***
- ***Alternative PI (listed alphabetically):***
  - ***Atazanavir in combination with low-dose ritonavir and two NRTIs for children age ≥6 years (AI*).***
  - ***Darunavir in combination with low-dose ritonavir and two NRTIs for children ≥6 years (AI*).***
  - ***Fosamprenavir in combination with low-dose ritonavir and two NRTIs for children age ≥6 years (AI*).***
- ***Use in special circumstances:***
  - ***Atazanavir unboosted (for treatment-naïve adolescents age ≥13 years and >39 kg who are unable to tolerate ritonavir) in combination with two NRTIs (unboosted atazanavir should not be used with tenofovir) (BII*).***
  - ***Fosamprenavir unboosted (for children age ≥2 years) in combination with two NRTIs (BIII).***
  - ***Nelfinavir in combination with two NRTIs (for children age >2 years) (BI*).***

The Panel does not recommend including the following PIs in initial therapy in children because of insufficient data, data related to toxicity or potency, or inconvenient dosing:

- ***Indinavir, saquinavir, or tipranavir (AIII).***
- ***Dual (full-dose) PIs (AIII).***
- ***Full-dose ritonavir or use of ritonavir as the sole PI (AIII).***
- ***Unboosted atazanavir in children age <13 years and/or <39 kg (AIII).***
- ***Nelfinavir in children age <2 years (AII).***
- ***Unboosted darunavir (AIII).***
- ***Once-daily dosing of lopinavir/ritonavir, boosted darunavir, or boosted or unboosted fosamprenavir (AII).***

Summary: PI-Based Regimens

Nine PIs are currently approved for use, 7 of which are approved for use in children and have pediatric drug formulations. Advantages and disadvantages of different PIs are delineated in **Table 12**. Advantages of PI-based regimens include excellent virologic potency, high barrier for development of drug resistance (requires multiple mutations), and sparing of the NNRTI drug class. However, the drugs have potential for multiple drug interactions due to metabolism via hepatic enzymes and may be associated with metabolic complications such as dyslipidemia, fat maldistribution, and insulin resistance. Factors to be considered in selecting a PI-based regimen for treatment-naïve children include virologic potency, dosing frequency, pill burden, food or fluid requirements, availability of palatable pediatric formulations, drug interaction profile, toxicity profile (particularly related to metabolic complications), and availability of data in children (see **Table 12** for advantages and disadvantages and **Appendix B: Pediatric Antiretroviral Drug Information** for detailed pediatric information on each drug).

Ritonavir acts as a potent inhibitor of the cytochrome P450 3A4 (CYP3A4) isoenzyme, thereby inhibiting the metabolism of other PIs, and has been used in low doses combined with another PI as a "pharmacokinetic booster," increasing drug exposure by prolonging the second drug's half-life. Boosted PI-based regimens are commonly used in treatment of adults, but adequate pediatric data are only available for coformulated lopinavir/ritonavir in children older than 6 weeks of age *[54]* and for atazanavir, fosamprenavir, darunavir, and

tipranavir with low-dose ritonavir in children age ≥6 years. Additionally, the use of low-dose ritonavir increases the potential for hyperlipidemia *[55]* and drug-drug interactions.

The Panel recommends coformulated lopinavir/ritonavir as the preferred PI for the treatment-naïve child based on virologic potency in adult and pediatric studies, high barrier to development of drug resistance, excellent toxicity profile in adults and children, availability of appropriate dosing information for children as young as age 6 weeks, and extensive experience as initial therapy in both resource-rich and resource-limited areas. However, data comparing the efficacy of lopinavir/ritonavir to other PIs are not available in children. Three PIs can be considered as alternative PIs for use in children age ≥6 years when used in combination with low-dose ritonavir: atazanavir, darunavir, and fosamprenavir. Other PIs that can be considered in special circumstances when preferred and alternative drugs are not available or are not tolerated include fosamprenavir without boosting ritonavir in children age ≥2 years, atazanavir without boosting ritonavir in adolescents age ≥13 years and >39 kg, and nelfinavir in children age ≥2 years. A saquinavir/ritonavir (1,000/100 mg twice daily)-based regimen compared with a lopinavir/ritonavir-based regimen demonstrated comparable virologic and immunologic outcomes when used as initial therapy in treatment-naïve adults *[56]* and is recommended as an alternative PI for initial therapy in the guidelines for adults and adolescents *[24]*. However, saquinavir is not recommended for initial therapy in children because there is no pediatric formulation and there are limited dosing and outcome data in children. Although good virologic and immunologic responses have been observed with indinavir-based regimens in adults, there is no liquid formulation and there has been a high rate of hematuria, sterile leukocyturia, and nephrolithiasis reported in pediatric patients with this drug *[57-60]*. The incidence of hematuria and nephrolithiasis with indinavir therapy may be higher in children than adults *[57, 60]*. Therefore, indinavir alone or with ritonavir boosting is not recommended as initial therapy. Additionally, tipranavir is not recommended for initial therapy at the present time due to limited experience in treatment-naïve children, but it may be considered for use with treatment failure.

Due to the limited data on pharmacokinetics of full-dose dual PI combination regimens in children (e.g., saquinavir plus coformulated lopinavir/ritonavir or plus nelfinavir) *[61-63]*, these combinations are not recommended as initial therapy in children, although they may have utility as components of secondary regimens for children who have failed initial therapy.

Lopinavir/ritonavir as preferred PI: In clinical trials in adults, regimens containing lopinavir/ritonavir plus 2 NRTIs have been found to have potent virologic activity in treatment-naïve patients. In a comparative trial of lopinavir/ritonavir versus nelfinavir (both combined with stavudine/lamivudine), lopinavir/ritonavir had superior virologic efficacy to nelfinavir (plasma HIV RNA <400 copies/mL in 84% vs. 66% of patients, respectively), and drug-resistant virus in patients with detectable plasma viral load at 48 weeks was detected in none of 51 lopinavir/ritonavir-treated patients, compared with 45% of 43 nelfinavir-treated patients *[64-65]*. The rate of toxicity was similar between the groups. Lopinavir/ritonavir has been studied in both antiretroviral-naïve and -experienced children and has demonstrated durable virologic activity and low toxicity *[5, 15, 54, 66-68]*. In a study of 44 treatment-naïve children, 84% had plasma HIV RNA <400 copies/mL and 71% <50 copies/mL after 48 weeks of therapy (see **Appendix B: Pediatric Antiretroviral Drug Information** for detailed information) *[68]*. In addition, dosing and efficacy data in infants as young as 6 weeks of age are available *[5, 54, 69]*. Although once-daily lopinavir/ritonavir is FDA approved for initial therapy in adults, pharmacokinetic data in children do not support a recommendation for once-daily dosing in children *[70-71]*.

Atazanavir with low-dose ritonavir as alternative PI (for children ≥6 years): Atazanavir is a once-daily PI that was approved for use in children ≥6 years of age in March 2008. It has equivalent efficacy to efavirenz-based and lopinavir/ritonavir-based combination therapy when given in combination with zidovudine and lamivudine in treatment-naïve adults *[72-73]*. Seventy-three percent of 48 treatment-naïve South African children achieved viral load <400 copies/mL by 48 weeks when given atazanavir with or without low-dose ritonavir in combination with 2 NRTIs *[74]*. Among 41 treatment-naïve children age 6–18 in IMPAACT/PACTG P1020A who received the capsule formulation of atazanavir with or without ritonavir, 68% and 59% achieved viral load <400 copies/mL and <50copies/mL, respectively, by 48 weeks *[75]*. When given with low-dose ritonavir boosting, atazanavir achieves enhanced concentrations compared with the unboosted drug in adults and children ≥6 years of age *[76-77]* and in antiretroviral-naïve adults appears to be associated with fewer PI resistance mutations at virologic failure compared with atazanavir given without

ritonavir boosting *[78]*. The main adverse effect associated with atazanavir/low-dose ritonavir is indirect hyperbilirubinemia, with or without jaundice or scleral icterus, but without concomitant hepatic transaminase elevations. Although atazanavir is associated with fewer lipid abnormalities than other PIs, lipid levels are higher when using low-dose ritonavir boosting than atazanavir alone *[55]*.

Darunavir with low-dose ritonavir as alternative PI (for children ≥6 years): Darunavir combined with low-dose ritonavir boosting is approved for antiretroviral-naïve and -experienced adults and for children age ≥6 years. Darunavir/ritonavir (800/100 mg once daily) has been found to be noninferior to lopinavir/ritonavir (once or twice daily), both in combination with tenofovir/emtricitabine, in an adult randomized, open-label trial. Plasma HIV RNA levels were <50 copies/mL in 84% of darunavir/ritonavir recipients and in 78% of lopinavir/ritonavir recipients ($p < 0.001$). Adverse events were also less common in the darunavir/ritonavir group ($p < 0.01$) *[79]*. There are no published data about use of darunavir as part of initial treatment in children or use of once-daily darunavir in children. In a study of treatment-experienced children (6–17 years of age), twice-daily darunavir/ritonavir-based therapy was well tolerated and resulted in 48% achieving HIV-1 RNA less than 50 copies/mL, by 48 weeks *[80]*. Darunavir with low-dose ritonavir is recommended as an alternative initial therapy in HIV-infected children based on data from one study in treatment-experienced children and the finding of high potency and low toxicity in adults. Some experts would only recommend boosted darunavir for treatment-experienced children and reserve its use for patients with PI resistant mutations. Once-daily dosing of darunavir is not recommended for children.

Fosamprenavir with low-dose ritonavir as alternative PI (for children ≥6 years): Fosamprenavir (the prodrug of amprenavir) is now available in a pediatric liquid formulation and a tablet formulation. Amprenavir is no longer manufactured. In June 2007, fosamprenavir suspension was approved for use in pediatric patients ≥2 years of age. The approval was based on two open-label studies in pediatric patients between 2 and 18 years of age *[81-82]*. Overall, fosamprenavir was well tolerated and effective in suppressing viral load and increasing CD4 cell count (see **Appendix B: Pediatric Antiretroviral Drug Information** for detailed information). There is less pediatric experience with fosamprenavir than with lopinavir/ritonavir. In an adult clinical trial, fosamprenavir with low-dose ritonavir was demonstrated to be noninferior to lopinavir/ritonavir r *[83]*. In children age ≥6 years, fosamprenavir should be used in combination with low-dose ritonavir boosting to ensure adequate drug levels. Data on appropriate dosing of fosamprenavir in combination with low-dose ritonavir in children age <6 years are not available; therefore, this combination cannot be recommended in that age group. Once-daily dosing of fosamprenavir is not recommended for pediatric patients.

PIs for use in special circumstances

Atazanavir without ritonavir boosting in children age ≥13 years: Although unboosted atazanavir is approved for treatment-naïve adolescents age ≥13 years and >39 kg who are unable to tolerate ritonavir, data from the ongoing IMPAACT/PACTG 1020A study indicate that higher doses (on a mg/m^2 basis) are required to achieve adequate drug concentrations (see **Appendix B: Pediatric Antiretroviral Drug Information** for detailed information on dosing used in IMPAACT/PACTG P1020A). If using unboosted atazanavir in treatment-naïve patients, clinicians should consider using a dual-NRTI combination other than didanosine/emtricitabine because of inferior virologic response demonstrated for this combination in adults in ACTG 5175 *[84]*. If these agents are to be used in combination, patients should be instructed to take them at least 2 hours apart, to take atazanavir with food, and to take didanosine on an empty stomach.

Fosamprenavir without ritonavir boosting in children age ≥2 years: Fosamprenavir without ritonavir boosting has been studied in children age ≥2 years but is only recommended in special circumstances when preferred or alternative PI-based regimens cannot be used.

Nelfinavir for children ≥2 year): Nelfinavir in combination with two NRTIs is an acceptable PI choice for initial treatment of children age ≥2 years in special circumstances. There is extensive pediatric experience with nelfinavir-based regimens in antiretroviral-naïve and -experienced children, with follow-up in children receiving the regimen for as long as 7 years *[85]*. The drug has been well tolerated, with diarrhea as the primary side effect, but virologic potency has been highly variable between studies, with reported rates of virologic suppression ranging 26%–69% (see **Appendix B: Pediatric Antiretroviral Drug Information** for

detailed information). Several studies have shown a correlation between nelfinavir trough concentrations and virologic response in treatment-naïve pediatric patients *[86]*. In one such study, virologic response at Week 48 was observed in 29% of children with subtherapeutic nelfinavir troughs (<0.8 mg/L) versus 80% in children with therapeutic nelfinavir troughs (>0.8 mg/L) *[86]*. There is large interpatient variability in plasma concentrations in children, with lower levels in younger children *[87-92]*. The optimal dose of nelfinavir in younger children, particularly those age <2 years, has not been well defined, and higher doses of nelfinavir (relative to body size) are required to achieve adequate drug levels in infants than in older children *[87]*. Pharmacokinetic parameters in adolescent patients have not been well studied, and doses higher than those recommended in adults may be required for some patients. These data, combined with data in adults showing lesser potency of nelfinavir compared with other protease inhibitors and efavirenz, balanced against the advantage of a protease inhibitor that is not coadminstered with low-dose ritonavir for boosting *[65, 93-96]*, make nelfinavir an agent for use in special circumstances in treatment-naïve children age ≥2 years and not recommended for treatment of children age <2 years.

The pediatric powder formulation of nelfinavir has a poor acceptance rate when mixed with food or formula, and the pharmacokinetics of the drug is extremely variable in children. To overcome the problems associated with this formulation, tablets are dissolved in water or other liquids to make a slurry that is then ingested by children unable to swallow whole tablets. Dissolving nelfinavir tablets in water and swallowing whole tablets resulted in comparable pharmacokinetic parameters in a study in adults *[97]*.

Triple-NRTI Regimens

Panel's Recommendations:

- ***Preferred: None***
- ***Alternative: None***
- ***Use in special circumstances:***
  - ***A three-NRTI-based regimen consisting of zidovudine + lamivudine + abacavir should be used only in special circumstances when a preferred or alternative NNRTI-based or PI-based regimen cannot be used as first-line therapy in treatment-naïve children (e.g., due to significant drug interactions or adherence concerns) (BI*).***

The Panel does not recommend any other triple-NRTI regimens as initial therapy in children due to inferior virologic potency or lack of comparative data (AIII).

Summary: Triple-NRTI Regimens

Triple-NRTI regimens are attractive for use in HIV-infected pediatric patients as initial therapy because of the ease of administration, availability of palatable liquid formulations, demonstrated tolerance, and avoidance of many drug interactions. Data on the efficacy of triple-NRTI regimens for treatment of antiretroviral-naïve children are limited; in small observational studies, response rates of 47%–50% have been reported *[98-99]*. In adult trials, these regimens have shown less potent virologic activity when compared with NNRTI- or PI-based regimens. Based on the results of these clinical trials, the Panel recommends that a three-NRTI-based regimen consisting of zidovudine + lamivudine + abacavir should be used only in special circumstances when a preferred or alternative NNRTI-based or PI-based regimen cannot be used as first-line therapy in treatment-naïve children (e.g., due to significant drug interactions or concerns related to adherence).

Following is a discussion of findings in clinical trials of triple-NRTI regimens:

Zidovudine + lamivudine + abacavir: In a randomized trial, the triple-NRTI combination of zidovudine + lamivudine + abacavir was shown to reduce viral load to <400 copies/mL in 51% of treatment-naïve adults at 48 weeks of therapy, results equivalent to those of the PI-based comparison arm of zidovudine + lamivudine + indinavir *[100]*. In a study of this regimen in previously treated children, the combination showed evidence of only modest viral suppression, with only 10% of 102 children maintaining a viral load of <400 copies/mL at

48 weeks of treatment *[101]*. Additionally, a clinical trial (ACTG 5095) in antiretroviral-naïve adults that compared initial therapy with abacavir + zidovudine + lamivudine to efavirenz + zidovudine + lamivudine or efavirenz + abacavir + zidovudine + lamivudine found that the triple-NRTI regimen was inferior to the efavirenz-based regimens, with a higher incidence of and an earlier time to virologic failure; after 48 weeks of therapy, 74% of adults receiving the triple-NRTI regimen had HIV RNA <200 copies/mL, compared with 89% of patients receiving efavirenz-based regimens *[26, 102]*.

Other triple-NRTI regimens: Clinical trials in adults also have investigated triple-NRTI regimens consisting of stavudine + didanosine + lamivudine, stavudine + lamivudine + abacavir, and didanosine + stavudine + abacavir *[103-104]*. The virologic response to all these regimens was inferior to viral suppression achieved in comparator regimens. In addition, the M184V lamivudine drug-resistance mutation was seen more frequently in patients treated with triple-NRTI regimens containing lamivudine. Triple-NRTI regimens containing tenofovir have been studied in adults. Tenofovir + abacavir + lamivudine and tenofovir + didanosine + lamivudine demonstrate significantly increased rates of virologic failure and are not recommended *[105-107]*. Tenofovir + zidovudine + lamivudine combination demonstrated antiviral activity in adults but no comparative data are available and the regimen is not recommended *[108]*.

Selection of Dual-NRTI Backbone as Part of Initial Combination Therapy

Panel's Recommendations (listed alphabetically):

- ***Preferred two-NRTI backbone combinations:***
  - ***Abacavir + (lamivudine or emtricitabine) (AI).***
    - ***HLA-B*5701 genetic testing should be performed prior to initiating abacavir-based therapy, and abacavir should not be given to a child who tests positive for HLA-B*5701 (AII*).***
  - ***Didanosine + (lamivudine or emtricitabine) (BI*).***
  - ***Zidovudine + (lamivudine or emtricitabine) (AI*).***
  - ***For postpubertal or Tanner stage 4 adolescents only: tenofovir + (lamivudine or emtricitabine) (A-I*).***
- ***Alternative two-NRTI backbone combinations:***
  - ***Zidovudine + (abacavir or didanosine) (BII).***
- ***Use in special circumstances:***
  - ***Stavudine + (lamivudine or emtricitabine) (BII).***

The Panel does not recommend the following dual-NRTI backbones for initial therapy in children:

- ***Stavudine + didanosine due to increased toxicity (AII).***
- ***Abacavir + didanosine, abacavir + tenofovir, and didanosine + tenofovir due to insufficient data (BIII).***
- ***Tenofovir as part of any dual-NRTI backbone in children in Tanner stages 1–3 due to lack of pediatric dosing data and formulation and concerns related to bone toxicity (BII).***

Summary: Selection of Dual-NRTI Backbone Regimen

Currently, six NRTIs (zidovudine, didanosine, lamivudine, stavudine, abacavir, and emtricitabine) are FDA approved for use in children younger than 13 years of age. Dual-NRTI combinations form the "backbone" of combination regimens for both adults and children. Dual-NRTI combinations that have been studied in children include zidovudine in combination with abacavir, didanosine, or lamivudine; abacavir in combination with lamivudine, stavudine, or didanosine; and emtricitabine in combination with stavudine or didanosine *[6, 37, 85, 91, 109-110]*. Advantages and disadvantages of different dual-NRTI backbone options are delineated in **Table 10**.

The preferred dual-NRTI combinations for initial therapy in children consist of abacavir, didanosine, or zidovudine combined with either lamivudine or emtricitabine. The most extensive experience in children is with zidovudine in combination with lamivudine. This combination has extensive data on safety in children and is generally well tolerated. The major toxicities are bone marrow suppression, manifested as macrocytic anemia and neutropenia. Minor toxicities include gastrointestinal toxicity and fatigue. The combination of zidovudine and didanosine had the lowest rate of toxicities in a large retrospective study of children *[111]*.

Both lamivudine and emtricitabine are well tolerated with few side effects. Although there is less experience in children with emtricitabine than lamivudine, it is similar to lamivudine and can be substituted for lamivudine as one component of a preferred dual-NRTI backbone (i.e., emtricitabine in combination with abacavir, didanosine, or zidovudine). The advantages of emtricitabine are once-daily administration, ability to be coadministered with didanosine as a once-daily NRTI backbone option, and availability as an oral solution. Both lamivudine and emtricitabine select for the M184V resistance mutation, which is associated with high-level resistance to both drugs; a modest decrease in susceptibility to abacavir and didanosine; and improved susceptibility to zidovudine, stavudine, and tenofovir *[112-113]*.

Abacavir in combination with lamivudine has been shown to be as potent or possibly more potent than zidovudine in combination with lamivudine in both children and adults *[114-115]* but has the potential for abacavir-associated life-threatening hypersensitivity reactions in a small proportion of patients. In 5 years of follow-up, abacavir plus lamivudine maintained significantly better viral suppression and growth in children than did zidovudine plus lamivudine and zidovudine plus abacavir *[115]*. Abacavir hypersensitivity is more common in individuals with certain HLA genotypes, particularly HLA-B*5701 (see **Appendix B: Pediatric Antiretroviral Drug Information**); however the prevalence of HLA-B*5701 is much lower in African American and Hispanic than white individuals in the United States (2%–2.5% compared with 8%) *[116]*. Pretreatment screening for HLA-B*5701 prior to initiation of abacavir treatment resulted in a significant reduction in the rate of abacavir hypersensitivity reaction in HIV-infected adults (from 7.8% to 3.4%) *[117]*. Genetic screening for HLA-B*5701 should be performed for HIV-infected children prior to initiating abacavir-based therapy and abacavir should not be given to those who test positive for HLA-B*5701.

Didanosine in combination with lamivudine or emtricitabine are also preferred dual-NRTI combinations. The combination of didanosine and emtricitabine allows for once-daily dosing. In a study of 37 treatment-naïve children age 3 to 21 years, long-term virologic suppression was achieved with a once-daily regimen of didanosine, emtricitabine, and efavirenz; 72% of subjects maintained HIV RNA suppression to <50 copies/mL through 96 weeks of therapy *[37]*. Prescribing information for didanosine recommends administration on an empty stomach. However, this is impractical for infants who feed frequently and may decrease medication compliance in older children by increasing regimen complexity. A comparison of didanosine given with or without food in children found that systemic exposure was similar but with slower and more prolonged absorption with food *[118]*. To improve compliance, some practitioners recommend administration without regard to timing of meals for young children. However, data are inadequate to allow a strong recommendation at this time, and it is preferred that didanosine be administered under fasting conditions when possible.

Tenofovir has been studied in HIV-infected children in combination with other NRTIs and as an investigational oral sprinkle/granule formulation *[119-122]*. Tenofovir in combination with lamivudine or emtricitabine is a preferred dual-NRTI combination for use in adolescents in Tanner stage 4 or who are postpuberty. The fixed-dose combinations of tenofovir + emtricitabine and tenofovir + emtricitabine + efavirenz are both administered as 1 pill once daily and may be particularly useful to improve adherence in older adolescents. In studies in adults, tenofovir when used with lamivudine or emtricitabine in combination with efavirenz had potent viral suppression for up to 3 years and was superior to zidovudine/lamivudine/efavirenz in viral efficacy *[123-124]*. In ACTG 5202, adults were randomly assigned to tenofovir + emtricitabine versus abacavir + lamivudine in combination with boosted atazanavir versus efavirenz (in factorial design). Among those with screening HIV-1 RNA ≥100,000 copies per mL, the times to virologic failure and to first adverse event were both significantly shorter in patients randomly assigned to abacavir + lamivudine than in those assigned to tenofovir + emtricitabine. Results for patients with lower entry viral loads and for comparisons by assignment to efavirenz or boosted atazanavir are not yet available *[125]*. In other nonrandomized studies, 48-week virologic efficacy of tenofovir + emtricitabine in combination with

lopinavir/ritonavir was similar to that seen in trials with other dual-NRTI backbones in treatment-naïve adults *[126]*. However, decreases in bone mineral density have been shown in both adults and children taking tenofovir for 48 weeks in some, although not all, studies *[119-122, 127]*. At this time data are insufficient to recommend use of this drug for initial therapy in infected children in Tanner stages 1–3, in whom the risk of bone toxicity may be greatest *[119, 122]* (see **Appendix B: Pediatric Antiretroviral Drug Information** for more detailed pediatric information). Renal toxicity has been reported in children as well as adults receiving tenofovir; in 1 single-center study, the rate of beta-2-microglobulinuria was higher in children receiving tenofovir than children receiving other antiretroviral agents (12/44 compared with 2/48, respectively), although creatinine clearance did not differ between groups *[128]*. Because of potential bone toxicity and renal toxicity, the drug may have greater utility for treatment of children in whom other antiretroviral drugs have failed than for initial therapy of treatment-naïve children. There are numerous drug-drug interactions with tenofovir and other antiretroviral drugs, including didanosine, lopinavir/ritonavir, atazanavir, and tipranavir, that complicate appropriate dosing of this drug.

Alternative dual-NRTI combinations include zidovudine in combination with abacavir or didanosine. There is considerable experience with use of these dual-NRTI regimens in children *[111]*. However, both zidovudine + abacavir and zidovudine + lamivudine had lower rates of viral suppression and more toxicity leading to drug modification than did abacavir + lamivudine in one European pediatric study *[91, 115]*.

The dual-NRTI combination of stavudine with lamivudine or emtricitabine is recommended for use only in special circumstances because stavudine is associated with a higher risk of lipoatrophy and hyperlactatemia than other NRTI drugs *[129-131]*. Children receiving dual-NRTI combinations containing stavudine had higher rates of clinical and laboratory toxicities than those receiving zidovudine-containing combinations *[111]*. In children with anemia in whom there are concerns related to abacavir hypersensitivity and who are too young to receive tenofovir, stavudine may be preferred to zidovudine for initial therapy because of its lower incidence of hematologic toxicity.

Certain dual-NRTI drug combinations are not recommended. These include zidovudine + stavudine due to pharmacologic interactions that can result in potential virologic antagonism. The drug structure of emtricitabine is similar to lamivudine and the same single resistance mutation confers cross resistance, so these drugs should not be used in combination. The dual-NRTI combination of stavudine + didanosine is also not recommended for use as initial therapy. In small pediatric studies, stavudine + didanosine demonstrated virologic efficacy and was well tolerated *[109-110, 132]*. However, in studies in adults, stavudine + didanosine-based combination regimens were associated with greater rates of neurotoxicity, pancreatitis, hyperlactatemia and lactic acidosis, and lipodystrophy than therapies based on zidovudine + lamivudine *[133-134]*; additionally, cases of fatal and nonfatal lactic acidosis with pancreatitis/hepatic steatosis have been reported in women receiving this combination during pregnancy *[129, 135]*. Abacavir + didanosine, abacavir + tenofovir, and didanosine + tenofovir are not recommended as dual-NRTI backbones in initial therapy on the basis of insufficient data in children.

***Not* Recommended for *Initial* Therapy for Children Because of Insufficient Data**

Panel's Recommendations:

Because of insufficient data for use as initial therapy, the following regimens (in addition to those already discussed in previous sections) should not be offered to children for initial therapy (AIII):

- ***Triple-class regimens, including NRTI plus NNRTI plus PI***
- ***Maraviroc-containing regimens***
- ***Raltegravir-containing regimens***
- ***Enfuvirtide (T-20)-containing regimens***

A number of antiretroviral drugs and drug regimens are not recommended for initial therapy of antiretroviral-naïve children because of insufficient pediatric data. These are summarized below.

Regimens containing three drug classes: Data are insufficient to recommend initial regimens containing agents from three drug classes (e.g., NRTI plus NNRTI plus PI). Although efavirenz plus nelfinavir plus one or two NRTIs was shown to be safe and effective in HIV-infected children with prior NRTI therapy, this regimen was not studied as initial therapy in treatment-naïve children and has the potential for inducing resistance to three drug classes, which could severely limit future treatment options *[38-40]*.

New agents without sufficient pediatric data for use as initial therapy (Tables 13 and 14): At this time several new agents appear promising in adults but do not have sufficient pediatric pharmacokinetic and safety data to recommend their use as components of an initial therapeutic regimen in children. These include maraviroc (a CCR5 antagonist), raltegravir (an integrase inhibitor), tenofovir (in children Tanner stages 1–3), and etravirine (a new NNRTI). Raltegravir is being evaluated in treatment-experienced children, but pharmacokinetic, safety, and efficacy data are not yet available and no pediatric formulation is commercially available. Tipranavir boosted with ritonavir was approved (June 2008) by the FDA for use in treatment-experienced children age 2–18 years, but data are insufficient to address use as initial therapy.

Enfuvirtide (T-20), a fusion inhibitor, is approved for use in children age ≥6 years in combination with other antiretroviral drugs in treatment-experienced patients with evidence of HIV replication despite ongoing antiretroviral therapy. The drug must be administered subcutaneously twice daily and is associated with a high incidence of local injection site reactions (98%). Data are currently insufficient to recommend use of enfuvirtide for initial therapy of children.

Antiretroviral Drug Regimens that Should Never be Offered (Table 9)

Panel's Recommendations:

The following regimens or regimen components should never be offered to HIV-infected children:

- ***Monotherapy (AII)***
- ***Two NRTIs alone (AI)***
- ***Certain two-NRTI combinations as part of a combination regimen:***
  - ***Lamivudine + emtricitabine due to similar resistance pattern and no additive benefit (AIII)***
  - ***Zidovudine + stavudine due to virologic antagonism (AII)***
- ***Dual-NNRTI combinations (AI*)***
- ***Unboosted saquinavir, darunavir, or tipranavir (AII*)***
- ***Atazanavir + indinavir (AIII)***
- ***Certain NRTI-only regimens***
  - ***Tenofovir + didanosine + (lamivudine or emtricitabine) (AI*)***
  - ***Tenofovir + abacavir + (lamivudine or emtricitabine) (AI*)***

Several antiretroviral drugs and drug regimens are not recommended for use in therapy of children or adults. These are summarized below. Clinicians should be aware of the components of fixed-drug combinations so that patients do not inadvertently receive a double dose of a drug contained in such a combination.

Monotherapy: Therapy with a single antiretroviral drug is not recommended because it is unlikely to result in sustained viral suppression, leading to the development of viral resistance to the drug being used and cross resistance to other drugs within the same drug class. The exception is for prophylaxis for the newborn infant born to an HIV-infected mother, in which case 6 weeks of monotherapy with zidovudine is recommended for the infant (unless the infant is identified as HIV infected, in which case zidovudine should be discontinued and standard triple therapy instituted) *[24]*.

Dual-nucleoside regimens alone: Dual-NRTI therapy alone is not recommended for initial therapy because it is unlikely to result in sustained viral suppression, leading to the development of viral resistance to the drugs being used and cross resistance to other drugs within the same drug class. For children previously initiated on a

dual-NRTI regimen who have achieved viral suppression, it is reasonable to either continue on this therapy or to add a PI or NNRTI to the regimen. If a child is to stay on a two-NRTI regimen, the plan should be to change to a three or more drug combination if viral rebound should occur (see **Antiretroviral Treatment Failure in Infants, Children, and Adolescents**).

In special circumstances of children with treatment failure associated with drug resistance and persistent nonadherence, there may be a role for use of single- or dual-NRTI regimens as holding or bridging regimens, while intensively working on improving adherence in preparation for initiation of a new, suppressive combination antiretroviral regimen (see section on **Approach to the Management of Antiretroviral Treatment Failure**).

Certain dual-nucleoside backbone combinations: Certain dual-NRTI combinations (zidovudine + stavudine, emtricitabine + lamivudine) are not recommended for therapy at any time because of pharmacological antagonism or inferior virologic response. Emtricitabine should not be used in combination with lamivudine because the drug structure is similar and the same single resistance mutation (M184V) induces resistance to both drugs.

Dual non-nucleoside reverse transcriptase inhibitors (NNRTIs): An adult study (2NN) demonstrated increased toxicity with the combination of nevirapine plus efavirenz *[34]*.

Certain PIs: The combination of atazanavir + indinavir has the potential for additive hyperbilirubinemia. Unboosted saquinavir, darunavir, and tipranivir have low bioavailablity and do not achieve adequate drug levels, and therefore should not be used without ritonavir boosting.

Three-NRTI regimen of tenofovir + (didanosine or abacavir) + (lamivudine or emtricitabine): The triple-NRTI combinations of tenofovir with (didanosine or abacavir) plus (lamivudine or emtricitabine) have a high rate of early virologic nonresponse when used as initial therapy in treatment-naïve adults and are not recommended as combination therapy for children at any time *[105-107]*.

Table 8. Antiretroviral Regimens Recommended for Initial Therapy for Human Immunodeficiency Virus (HIV) Infection in Children

A combination antiretroviral regimen in treatment-naïve children generally contains 1 NNRTI plus a 2-NRTI backbone or 1 PI plus a 2-NRTI backbone. A 3-NRTI regimen consisting of zidovudine, abacavir, and lamivudine is recommended only if a PI or NNRTI regimen cannot be used. Regimens should be individualized based on advantages and disadvantages of each combination (see **Tables 11–13**).

Preferred Regimens	
Children <3 years of age:	Two NRTIs ***plus*** lopinavir/ritonavir[3]
	Two NRTIs ***plus*** nevirapine[1,3] (only if no peripartum nevirapine exposure)
Children ≥3 years of age:	Two NRTIs ***plus*** lopinavir/ritonavir[3]
	Two NRTIs ***plus*** efavirenz[1]
Alternative Regimens	
Children <3 years of age:	None
Children ≥3 to <6 years of age:	Two NRTIs ***plus*** nevirapine[1,3]
Children ≥6 years of age	Two NRTIs ***plus*** atazanavir ***plus*** low-dose ritonavir
	Two NRTIs ***plus*** darunavir ***plus*** low-dose ritonavir
	Two NRTIs ***plus*** fosamprenavir ***plus*** low-dose ritonavir
	Two NRTIs ***plus*** nevirapine[1,3]
Use in Special Circumstances	
	Two NRTIs ***plus*** atazanavir unboosted (for treatment-naïve adolescents ≥13 years of age and >39 kg)
	Two NRTIs ***plus*** fosamprenavir unboosted (children ≥2 years of age)
	Two NRTIs ***plus*** nelfinavir (children ≥2 years of age)
	Zidovudine ***plus*** lamivudine ***plus*** abacavir
2-NRTI Backbone Options (for use in combination with additional drugs) (alphabetical ordering)	
Preferred	Abacavir ***plus*** (lamivudine ***or*** emtricitabine)
	Didanosine ***plus*** (lamivudine ***or*** emtricitabine)
	Tenofovir ***plus*** (lamivudine ***or*** emtricitabine) (for Tanner stage 4 or postpubertal adolescents only)
	Zidovudine ***plus*** (lamivudine ***or*** emtricitabine)
Alternative	Zidovudine ***plus*** abacavir
	Zidovudine ***plus*** didanosine
Use in Special Circumstances	Stavudine ***plus*** (lamivudine ***or*** emtricitabine)

Not Recommended for Initial Therapy
Etravirine-containing regimens
Efavirenz-containing regimens for children <3 years of age
Tipranavir-containing regimens
Saquinavir-containing regimens
Indinavir-containing regimens
Dual (full-dose) PI regimens
Full-dose ritonavir or use of ritonavir as the sole PI
Unboosted atazanavir-containing regimens in children <13 years of age and/or <39 kg
Nelfinavir-containing regimens for children <2 years old
Unboosted darunavir regimens using once-daily dosing of lopinavir/ritonavir, boosted darunavir, or fosamprenavir (boosted or unboosted)
Triple-NRTI regimens other than abacavir + zidovudine + lamivudine
Triple-class regimens, including NRTI *plus* NNRTI *plus* PI
Regimens with dual-NRTI backbones of abacavir + didanosine, abacavir + tenofovir, didanosine + tenofovir , and didanosine + stavudine
Tenofovir-containing regimens in children in Tanner stages 1–3
Maraviroc-containing regimens
Raltegravir-containing regimens
Enfuvirtide (T-20)-containing regimens

[1] Efavirenz is currently available only in capsule form and should be used only in children ≥3 years of age with weight ≥10 kg; nevirapine would be the preferred NNRTI for children age <3 years of age (excluding infants who were exposed to nevirapine as part of maternal-infant peripartum prophylaxis) or who require a liquid formulation. Unless adequate contraception can be ensured, efavirenz-based therapy is not recommended for adolescent females who are sexually active and may become pregnant.

[2] With the exception of lopinavir/ritonavir at all ages and atazanavir/ritonavir, fosamprenavir/ritonavir, and darunavir/ritonavir in children ≥6 years of age, use of other boosted PIs as a component of initial therapy is not recommended, although such regimens have utility as secondary treatment regimens for children who have failed initial therapy.

[3] For children <3 years of age, nevirapine is the preferred NNRTI when NNRTI-based therapy is used. However, lopinavir/ritonavir is preferred to nevirapine by many experts. Nevirapine should not be used in infants who have been exposed to nevirapine as part of maternal-infant prophylaxis.

[4] Nevirapine should not be used in postpubertal girls with CD4 count >250/mm^3, unless the benefit clearly outweighs the risk.

Table 9. Antiretroviral Regimens or Components that Should Never Be Offered for Treatment of Human Immunodeficiency Virus (HIV) Infection in Children

	Rationale	Exceptions
Antiretroviral regimens never recommended for children		
Monotherapy	• Rapid development of resistance • Inferior antiviral activity compared with combination with ≥3 antiretroviral drugs	• HIV-exposed infants (with negative viral testing) during 6-week period of prophylaxis to prevent perinatal transmission
Two NRTIs alone	• Rapid development of resistance • Inferior antiviral activity compared with combination with ≥3 antiretroviral drugs	• Not recommended for initial therapy; for patients currently on this treatment, some clinicians may opt to continue if virologic goals are achieved
Tenofovir ***plus*** abacavir ***plus*** lamivudine ***or*** emtricitabine as a triple-NRTI regimen	• High rate of early viral failure when this triple-NRTI regimen used as initial therapy in treatment-naïve adults	• No exception
Tenofovir ***plus*** didanosine ***plus*** lamivudine ***or*** emtricitabine as a triple-NRTI regimen	• High rate of early viral failure when this triple-NRTI regimen used as initial therapy in treatment-naïve adults	• No exception
Antiretroviral components never recommended as part of an antiretroviral regimen for children		
Atazanavir ***plus*** indinavir	• Potential additive hyperbilirubinemia	• No exception
Dual-NNRTI combinations	• Enhanced toxicity	• No exception
Dual-NRTI combinations:		
• Lamivudine ***plus*** emtricitabine	• Similar resistance profile and no additive benefit	• No exception
• Stavudine ***plus*** zidovudine	• Antagonistic effect on HIV	• No exception
Efavirenz in first trimester of pregnancy or for sexually active adolescent girls of childbearing potential when reliable contraception cannot be ensured	• Potential for teratogenicity	• When no other antiretroviral option is available and potential benefits outweigh risks
Nevirapine initiation in adolescent girls with CD4 >250 cells/mm^3 or adolescent boys with CD4 >400 cells/mm^3	• Increased incidence of symptomatic (including serious and potentially fatal) hepatic events in these patient groups	• Only if benefit clearly outweighs the risk
Unboosted saquinavir, darunavir, or tipranavir	• Poor oral bioavailablity • Inferior virologic activity compared with other protease inhibitors	• No exception

Table 10. Advantages and Disadvantages of Different Nucleoside or Nucleotide Analogue Reverse Transcriptase Inhibitor (NRTI, NtRTI) Backbone Combinations for Use in Highly Active Antiretroviral Combination Regimens for Initial Therapy in Children

	Advantages	Disadvantages
Preferred Combinations		
Abacavir ***plus*** lamivudine ***or*** emtricitabine	• Palatable liquid formulations • Can give with food • Abacavir and lamivudine are coformulated as a single pill for older/larger patients	• Risk of abacavir hypersensitivity reaction; perform HLA-B*5701 screening prior to initiation of abacavir treatment
Didanosine ***plus*** lamivudine ***or*** emtricitabine	• Delayed-release capsules of didanosine may allow once-daily dosing in older children able to swallow pills and who can receive adult dosing along with once-daily emtricitabine • Emtricitabine available as a palatable liquid formulation administered once daily	• Food effect (didanosine is recommended to be taken 1 hour before or 2 hours after food) – some experts give didanosine without regard to food in infants or when compliance is an issue (but can be coadministered with emtricitabine or lamivudine) • Limited pediatric experience using delayed-release didanosine capsules in younger children • Pancreatitis, neurotoxicity with didanosine
Zidovudine ***plus*** lamivudine ***or*** emtricitabine	• Extensive pediatric experience • Zidovudine and lamivudine are coformulated as single pill for older/larger patients • Palatable liquid formulations • Can give with food • Emtricitabine available as a palatable liquid formulation administered once daily	• Bone marrow suppression with zidovudine • Lipoatrophy with zidovudine
Tenofovir ***plus*** lamivudine ***or*** emtricitabine for Tanner stage 4 or postpubertal adolescents only	• Resistance slow to develop • Once-daily dosing for tenofovir • Less mitochondrial toxicity than other NRTIs • Can give with food • Bone toxicity may be less in postpubertal children • Tenofovir and emtricitabine are coformulated as single pill for older/larger patients	• No pediatric formulation of tenofovir • Limited pediatric experience • Potential bone and renal toxicity • Numerous drug-drug interactions with other ARV agents including didanosine, lopinavir/ritonavir, atazanavir, and tipranavir complicate appropriate dosing
Alternate Combinations		
Zidovudine ***plus*** abacavir	• Palatable liquid formulations • Can give with food	• Risk of abacavir hypersensitivity reaction; perform HLA-B*5701 screening prior to initiation of abacavir treatment • Bone marrow suppression and lipoatrophy with zidovudine
Zidovudine ***plus*** didanosine	• Extensive pediatric experience • Delayed-release capsules of didanosine may allow once-daily dosing of didanosine in older children able to swallow pills and who can receive adult dosing	• Bone marrow suppression and lipoatrophy with zidovudine • Pancreatitis, neurotoxicity with didanosine • Didanosine liquid formulation less palatable than lamivudine or emtricitabine liquid formulation • Food effect (recommended to take didanosine 1 hour before or 2 hours after food); some experts give didanosine without regard to food in infants or when compliance is an issue

	Advantages	Disadvantages
Use in Special Circumstances		
Stavudine ***plus*** lamivudine ***or*** emtricitabine	• Moderate pediatric experience • Palatable liquid formulations • Can give with food • Emtricitabine available as a palatable liquid formulation administered once daily	• Stavudine associated with higher incidence of hyperlactatemia/lactic acidosis, lipoatrophy, peripheral neuropathy, hyperlipidemia • Limited pediatric experience with stavudine plus emtricitabine
Not Recommended		
Tenofovir-containing regimens in children in Tanner stages 1–3	• Resistance slow to develop • Once-daily dosing for tenofovir (adults) • Less mitochondrial toxicity than other NRTIs • Can give with food	• No pediatric formulation of tenofovir • Limited PK data for tenofovir in children • Limited pediatric experience • Potential bone and renal toxicity; bone toxicity appears to be more frequent in younger children • Numerous drug-drug interactions with other ARV agents including didanosine, lopinavir/ritonavir, atazanavir, and tipranavir complicate appropriate dosing
Zidovudine ***plus*** stavudine	• None	• Pharmacologic and antiviral antagonism
Lamivudine ***plus*** emtricitabine	• None	• Similar drug structure • Single mutation (M184V) associated with resistance to both drugs
Stavudine ***plus*** Didanosine	• Has shown antiviral activity in small studies in children • Although not recommended for initial therapy, it may be considered for use in antiretroviral-experienced children who require a change in therapy	• Significant toxicities including lipoatrophy, peripheral neuropathy, hyperlactatemia including symptomatic and life-threatening lactic acidosis, hepatic steatosis, and pancreatitis

Table 11. Advantages and Disadvantages of Different Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs) for Use in Highly Active Antiretroviral Combination Regimens for Initial Therapy in Children

	Advantages	Disadvantages
General Issues		
NNRTI-Based Regimens	**NNRTI Class Advantages:** • Less dyslipidemia and fat maldistribution than protease inhibitors • Protease inhibitor sparing • Lower pill burden than protease inhibitors for those taking solid formulation; easier to use and adhere to than protease inhibitor-based regimens	**NNRTI Class Disadvantages:** • Single mutation can confer resistance, with cross resistance between efavirenz and nevirapine • Rare but serious and potentially life-threatening cases of skin rash, including Stevens-Johnson syndrome, and hepatic toxicity with all NNRTIs (but highest with nevirapine) • Potential for multiple drug interactions due to metabolism via hepatic enzymes (e.g., CYP3A4)
Preferred		
Efavirenz (for children ≥3 years of age and who can take capsules)	• Potent antiretroviral activity • Once-daily administration • Can give with food (but avoid high fat meals)	• Neuropsychiatric side effects (bedtime dosing to reduce central nervous system effects) • Rash (generally mild) • No commercially available liquid • No data on dosing for children age <3 years • Teratogenic in primates; use with caution in adolescent females of childbearing age
Nevirapine for children age <3 years who have not been exposed to nevirapine as part of maternal-infant prophylaxis or who require a liquid formulation	• Liquid formulation available • Dosing information for young infants available • Can give with food	• Higher incidence of rash/hypersensitivity reaction than other NNRTIs • Higher rates of serious hepatic toxicity than efavirenz • Decreased virologic response compared with efavirenz • Need to initiate therapy with a lower dose and increase in a stepwise fashion. This is to allow for auto-induction of nevirapine metabolism and is associated with a lower incidence of toxicity.
Alternative		
Nevirapine (for children age ≥3 years)	• Liquid formulation available • Dosing information for young infants available • Can give with food	• Higher incidence of rash/hypersensitivity reaction than other NNRTIs • Higher rates of serious hepatic toxicity than efavirenz • Decreased virologic response compared with efavirenz • Need to initiate therapy with a lower dose and increase in a stepwise fashion. This is to allow for auto-induction of nevirapine metabolism and is associated with a lower incidence of toxicity. • Twice-daily dosing

	Advantages	Disadvantages
Not Recommended		
Efavirenz (for children age <3 years)	• Potent antiretroviral activity • Once-daily administration • Can give with food (but avoid high fat meals)	• Neuropsychiatric side effects (bedtime dosing to reduce central nervous system effects) • Rash (generally mild) • No commercially available liquid • No data on dosing for children age <3 years • Teratogenic in primates; use with caution in adolescent females of childbearing age
Etravirine	• Three or more baseline NNRTI mutations result in a decreased virologic response • Patients with a history of NNRTI-related rash do not appear to be at increased risk of etravirine-related rash	• Limited data on pediatric dosing or safety • No pediatric formulation available • Food effect (should be given with food) • No data in treatment-naïve patients • Multiple drug interactions with PIs and other medications • Twice-daily dosing • Skin rash

Table 12. Advantages and Disadvantages of Different Protease Inhibitors (PIs) for Use in Highly Active Antiretroviral Combination Regimens for Initial Therapy in Children

	Advantages	Disadvantages
General Issues		
Protease Inhibitor-Based Regimens	**Protease Class Advantages:** • NNRTI sparing • Clinical, virologic, and immunologic efficacy well documented • Resistance to protease inhibitors requires multiple mutations • Targets HIV at 2 steps of viral replication (viral reverse transcriptase and protease enzymes)	**Protease Class Disadvantages:** • Metabolic complications including dyslipidemia, fat maldistribution, insulin resistance • Potential for multiple drug interactions due to metabolism via hepatic enzymes (e.g., CYP3A4) • Higher pill burden than NRTI- or NNRTI-based regimens for those taking solid formulations • Poor palatability of liquid preparations, which may affect adherence to treatment regimen
Preferred		
Lopinavir/ritonavir	• Coformulated liquid and tablet formulations • Tablets can be given without regard to food but may be better tolerated when taken with food or snack	• Poor palatability of liquid (bitter taste), although better than ritonavir alone • Food effect (liquid should be administered with food) • Ritonavir component associated with large number of drug interactions (see ritonavir) • Use with caution in patients with pre-existing conduction system defects (can prolong PR and QT interval of electrocardiogram)
Alternative		
Atazanavir in combination with low-dose ritonavir in children age ≥6 years	• Once-daily dosing • Atazanavir has less effect on triglyceride and total cholesterol levels than other PIs (but ritonavir boosting may be associated with elevations in these parameters)	• No liquid formulation • Food effect (should be administered with food) • Indirect hyperbilirubinemia common but asymptomatic • Use with caution in patients with pre-existing conduction system defects (can prolong PR interval of electrocardiogram)
Fosamprenavir in combination with low-dose ritonavir in children age ≥6 years	• Oral prodrug of amprenavir with lower pill burden • Pediatric formulation available • Can give with food	• Skin rash • More limited pediatric experience than preferred PI • Food effect (should be given with food) • Ritonavir component associated with large number of drug interactions (see ritonavir) • Contains sulfa moiety; potential for cross sensitivity between fosamprenavir and other drugs in sulfonamide class is unknown.
Darunavir in combination with low-dose ritonavir in children age ≥6 years	• Effective in PI-experienced children when given with low-dose ritonavir boosting	• Pediatric data limited to antiretroviral-experienced children • Pediatric pill burden high with current tablet dose formulations • No liquid formulation • Food effect (should be given with food) • Must be given with ritonavir boosting to achieve adequate plasma concentrations • Contains sulfa moiety; potential for cross sensitivity between darunavir and other drugs in sulfonamide class is unknown.

	Advantages	Disadvantages
Use in Special Circumstances		
Fosamprenavir (unboosted) in children age ≥2 years	• Oral prodrug of amprenavir with lower pill burden • Pediatric formulation available • Can give with food	• Skin rash • More limited pediatric experience than preferred PI • May require boosted regimen to achieve adequate plasma concentrations but pharmacokinetic data to define appropriate dosing not yet available
Atazanavir (unboosted) in treatment-naïve adolescents age ≥13 years and >39 kg who are unable to tolerate ritonavir	• Once-daily dosing • Less effect on triglyceride and total cholesterol levels than other PIs	• No liquid formulation • Food effect (should be administered with food) • Indirect hyperbilirubinemia common but asymptomatic • Use in caution in patients with pre-existing conduction system defects (can prolong PR interval of electrocardiogram) • May require ritonavir boosting in treatment-naïve adolescent patients to achieve adequate plasma concentrations • Unboosted atazanavir cannot be used with tenofovir
Nelfinavir in children age ≥2 years	• Powder formation (for liquid preparation or to be added to food) • Can give with food • Simplified 2 tablets (625 mg) twice-daily regimen has a reduced pill burden compared with other PI-containing regimens in older patients where the adult dose is appropriate	• Diarrhea • Powder formulation poorly tolerated • Food effect (should be administered with food) • Appropriate dosage for younger children not well defined • Need for 3 times daily dosing for younger children • Adolescents may require higher doses than adults • Less potent that boosted PIs
Not Recommended		
Atazanavir (unboosted) in children <13 years of age and/or <39 kg	• Once-daily dosing (>13 years) • Less effect on triglyceride and total cholesterol levels than other PIs	• Drug levels low if used without ritonavir boosting • No liquid formulation • Food effect (should be administered with food) • Indirect hyperbilirubinemia common but asymptomatic • Use in caution in patients with pre-existing conduction system defects (can prolong PR interval of electrocardiogram) • May require ritonavir boosting in treatment-naïve adolescent patients to achieve adequate plasma concentrations
Indinavir (unboosted or boosted)	• May be considered for use as component of a regimen in combination with low-dose ritonavir in postpubertal adolescents who weigh enough to receive adult dosing	• Only available in capsule • Possible higher incidence of nephrotoxicity in children • Requires 3 times daily dosing unless boosted with ritonavir • High fluid intake required to prevent nephrolithiasis • Food effect (should be taken 1 hour before or 2 hours after food) • Limited pediatric pharmacokinetic data
Tipranavir	• Effective in PI-experienced children and adults when given with low-dose ritonavir boosting • Liquid formulation	• Limited data in treatment-naïve patients • Food effect (should be administered with food) • Must be given with ritonavir boosting to achieve adequate plasma concentrations
Ritonavir (full dose)	• Liquid formulation • Can be given with food	• Poor palatability of liquid (bitter taste) • Gastrointestinal intolerance • Food effect (should be administered with food) • Largest number drug interactions (most potent inhibitor of CYP3A4)

Table 12: Advantages and Disadvantages of Different Protease Inhibitors (PIs) for Use in Highly Active Antiretroviral Combination Regimens for Initial Therapy in Children
Page 3 of 3

	Advantages	Disadvantages
Not Recommended (continued)		
Nelfinavir in children age <2 years	• Powder formation (for liquid preparation or to be added to food) • Can give with food • Simplified 2 tablets (625 mg) twice-daily regimen has a reduced pill burden compared with other PI-containing regimens in older patients where the adult dose is appropriate	• Diarrhea • Powder formulation poorly tolerated • Food effect (should be administered with food) • Appropriate dosage for younger children not well defined • Need for 3 times daily dosing for younger children • Adolescents may require higher doses than adults • Less potent that boosted PIs
Saquinavir (unboosted or boosted)		• Low bioavailability, should never be used as sole PI • Limited pediatric pharmacokinetic data; will require boosting with another PI (e.g., ritonavir) to achieve adequate concentrations • No liquid formulation • High pill burden • Must be taken with food • Photosensitivity reactions can occur

Table 13. Advantages and Disadvantages of Entry Inhibitors for Use in Highly Active Antiretroviral Combination Regimens

	Advantages	Disadvantages
General Issues		
Entry Inhibitors	**Entry Inhibitor Class Advantages:** • Susceptibility of HIV to a new class of ARVs	**Entry Inhibitor Class Disadvantages:** • Rapid development of resistance with enfuvirtide • CCR5 inhibitors ineffective against CXCR4 virus, mixed CCR5 and CXCR4 viral populations, or dual-tropic virus
Use in Special Circumstances		
Enfuvirtide	• Susceptibility of HIV to a new class of ARVs • Route of administration ensures adequate drug levels	• Twice-daily subcutaneous injections • 98%–100% incidence of local injection site reactions • Poor adherence and limited levels of success in adolescents due to local site reactions
Insufficient Data to Recommend		
Maraviroc	• Susceptibility of HIV to a new class of ARVs • Can give with food	• Ineffective against CXCR4 or mixed/dual-tropic viral populations • Limited data on pediatric dosing or safety • No pediatric formulation • Multiple drug interactions; different dosing depending on which NNRTI or PI is coadministered

Table 14. Advantages and Disadvantages of Integrase Inhibitors for Use in Highly Active Antiretroviral Combination Regimens

	Advantages	Disadvantages
General Issues		
Integrase Inhibitors	**Integrase Inhibitor Class Advantages:** • Susceptibility of HIV to a new class of ARVs	**Integrase Inhibitor Class Disadvantages:** • Limited data on pediatric dosing or safety
Insufficient Data to Recommend		
Raltegravir	• Susceptibility of HIV to a new class of ARVs • Can give with food	• Limited data on pediatric dosing or safety • No pediatric formulation • Rare systemic allergic reaction or hepatitis

Monitoring of Children on Antiretroviral Therapy (Updated August 16, 2010)

Panel's Recommendations:

- ***Children who start a new antiretroviral regimen should be evaluated in person or by phone within 1 to 2 weeks of starting medication to screen for clinical side effects and to ensure patient adherence to the regimen (AIII).***
- ***Children should be evaluated within 4 to 8 weeks to assess for possible side effects and to evaluate initial response to therapy (AIII). More frequent evaluation may be needed following initiation or change in therapy to support adherence to the regimen (AIII).***
- ***Subsequently, children should have a monitoring evaluation at least every 3 to 4 months to assess both efficacy and potential toxicity of their antiretroviral regimens (AII*).***

Children who start a new antiretroviral regimen or who change to a new regimen should be followed to assess effectiveness, adherence, tolerability, and side effects of the regimen. Frequent patient visits and intensive follow-up during the initial months after a new antiretroviral regimen is started are necessary to support and educate the family. The first few weeks of antiretroviral therapy can be particularly difficult for children and their caregivers. They must adjust their schedules to allow for consistent and routine administration of medication doses. Children may also experience side effects of medications, and the child and caregivers need assistance in determining whether the effects are temporary and can be tolerated or whether they are more serious or long-term and necessitate a visit to the clinician. Thus, it is prudent for the clinician to assess the child within 1–2 weeks of initiating therapy, either in person or with a phone call, to assure proper administration of medications and to evaluate clinical concerns. Many clinicians will plan additional contact (in person or by telephone) with the child and caregivers during the first few weeks of therapy to support adherence.

Baseline laboratory assessments should be done prior to initiation of therapy; these include CD4 count/percentage and HIV RNA level; complete blood count and differential; serum chemistries (including electrolytes, BUN, creatinine, glucose, hepatic transaminases, calcium, and phosphorus); pancreatic enzyme evaluations (amylase, lipase) if therapy is being initiated with a drug with potential pancreatic toxicity, such as didanosine; and serum lipid evaluation (cholesterol, triglycerides). The child should be seen within 4–8 weeks after initiating or changing therapy to obtain a clinical history, with a focus on potential adverse effects and to assess adherence to medications; perform a physical examination; evaluate efficacy of therapy (measurement of CD4 count/percentage and HIV RNA levels); and obtain a laboratory evaluation for toxicity. More frequent evaluation may be needed following a change in therapy to support adherence to the regimen. At a minimum, laboratory assessments should include a complete blood count and differential, serum chemistries, and assessment of renal and hepatic function. Assessment of initial virologic response to therapy is important because an initial decrease in HIV viral load in response to antiretroviral treatment should be observed after 4–8 weeks of therapy.

Subsequently, children taking antiretroviral medication should have assessments of adherence, toxicity, and efficacy at least every 3–4 months. **Table 15** provides one proposed monitoring schema, which will require adjustment based on the specific therapy the child is receiving. Assessments should include basic hematology, chemistry, CD4 count/percentage, and HIV viral load. Monitoring of drug toxicities should be tailored to the particular medications the child is taking; for example, periodic monitoring of pancreatic enzymes may be desirable in children receiving didanosine, or of serum glucose and lipids in patients receiving PIs. Children who develop symptoms of toxicity should have appropriate laboratory evaluations (e.g., evaluation of serum lactate in a child receiving NRTI drugs who develops symptoms suspicious for lactic acidosis) performed more frequently until the toxicity resolves. For further details of adverse effects associated with particular

antiretroviral medications, please see **Tables 17a–17h. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations**.

Table 15. Example of Minimum Schedule for Monitoring of Children on Antiretroviral Therapy

Time Schedule for Monitoring	Toxicity Monitoring[1]	Efficacy and Adherence Monitoring
Baseline (prior to initiation of therapy)	Clinical history, complete blood count and differential, chemistries[3]	CD4 cell count/percentage, HIV RNA
1–2 weeks[2]	Clinical history	Adherence screen
4–8 weeks	Clinical history, complete blood count and differential, chemistries[3]	CD4 cell count/percentage[4], HIV RNA, adherence screen
Every 3–4 months	Clinical history, complete blood count and differential, chemistries[3]	CD4 cell count/percentage, HIV RNA, adherence screen
Every 6–12 months	Lipid panel	

[1] For children receiving nevirapine, serum transaminase levels should be measured every 2 weeks for the first 4 weeks of therapy, then monthly for 3 months, followed by every 3 to 4 months.

[2] Children starting a new antiretroviral regimen should be evaluated in person or by phone within 1 to 2 weeks of starting medication to screen for clinical side effects and to ensure patient adherence to the regimen. Many clinicians will plan additional contacts (in person or by telephone) with the child and caregivers to support adherence during the first few weeks of therapy. Some clinicians also recommend an HIV RNA measurement within the initial weeks of therapy for an early assessment of response/adherence to therapy.

[3] Chemistries may include electrolytes, glucose, liver function tests (hepatic transaminases and bilirubin), renal function tests (BUN, creatinine), calcium, and phosphate. Additional evaluations should be tailored to the particular drugs the child is receiving; for example, pancreatic enzymes (amylase and lipase) may be considered if the child is starting drugs with potential pancreatic toxicity, such as didanosine.

[4] Some clinicians do not recommend a CD4 cell count/percentage at this time, considering it too early to expect an immunologic response.

Specific Issues in Antiretroviral Therapy for HIV-Infected Adolescents (Updated August 16, 2010)

***Panel's Recommendations*:**

- ***Antiretroviral therapy regimens must be individually tailored to the adolescent because those with perinatal exposure generally have a very different clinical course and treatment history than those who acquired HIV during adolescence (AIII).***
- ***Appropriate dosing of antiretroviral medications for adolescents is complex, not always predictable, and dependent upon multiple factors, including body mass and composition and chronologic age (AII).***
- ***Effective and appropriate contraceptive methods should be selected to reduce the likelihood of unintended pregnancy and prevent transmission of HIV (AI).***
- ***Providers should be aware of potential interactions between antiretroviral drugs and hormonal contraceptives, which could lower contraceptive efficacy (AII*).***
- ***Efavirenz should be avoided for the adolescent girl who desires to become pregnant or who does not use effective and consistent contraception (AII). Efavirenz also should be avoided throughout the first trimester of pregnancy (AII).***
- ***Pediatric and adolescent care providers should work with older adolescent patients to prepare them for transition into adult care settings (AIII).***

BACKGROUND

An increasing number of HIV-infected children who acquired HIV infection through perinatal transmission are now surviving into adolescence. They generally have had a long clinical course and extensive antiretroviral treatment history. Adolescents with behaviorally acquired infection (i.e., infection acquired via sexual activity or intravenous substance use) generally follow a clinical course that is similar to that of adults; they are in an earlier stage of infection, making them potential candidates for early intervention *[1]*.

DOSING OF ANTIRETROVIRAL THERAPY FOR HIV-INFECTED ADOLESCENTS

Puberty is a time of somatic growth and sexual maturation, with females developing more body fat and males more muscle mass. These physiologic changes may affect drug pharmacokinetics, which is especially important for drugs with a narrow therapeutic index that are used in combination with protein-bound medicines or hepatic enzyme inducers or inhibitors *[2]*. Dosages of medications for HIV infection and opportunistic infections traditionally have been prescribed according to Tanner staging of puberty *[3]* rather than strictly on the basis of age *[1]*. Using this method, adolescents in early puberty (Tanner stages I and II) are administered doses using pediatric schedules, whereas those in late puberty (Tanner stage V) are administered doses using adult schedules. However, Tanner stage and age are not necessarily directly predictive of drug pharmacokinetics. In addition, puberty may be delayed in perinatally HIV-infected children *[4]*, adding to discrepancies between Tanner stage-based dosing and age-based dosing.

Many antiretroviral medications (e.g., abacavir, emtricitabine, lamivudine, tenofovir, and some PIs) are administered to children at higher weight- or surface area-based doses than would be predicted by direct scaling of adult doses, based upon reported pharmacokinetic data indicating higher oral drug clearance in children. Continued use of these pediatric weight- or surface area-based doses as a child grows during adolescence can result in medication doses that are higher than the usual adult doses. Data suggesting optimal doses for every antiretroviral medication for adolescents are not available; **Appendix B: Pediatric Antiretroviral Drug Information** includes discussion of data relevant to adolescents for individual drugs and notes the age listed on the drug label for adult dosing, when available. Other factors, such as toxicity, pill

burden, adherence, and virologic and immunologic parameters, may also help determine when to transition adolescents from pediatric to adult doses.

ADOLESCENT CONTRACEPTION, PREGNANCY, AND ANTIRETROVIRAL THERAPY

Adolescents with HIV infection, regardless of mode of acquisition, may be sexually active. Contraception methods and safer sex techniques for prevention of HIV transmission should be discussed with them regularly (see **Incorporating HIV Prevention into the Medical Care of Persons Living with HIV**) *[5]*.

The possibility of planned or unplanned pregnancy should be a consideration when selecting an antiretroviral regimen for the adolescent girl. The most vulnerable period in fetal organogenesis is early in gestation, often before pregnancy is recognized. Sexual activity, reproductive plans, and use of effective contraception should be discussed with the patient. Efavirenz-containing regimens should be avoided in adolescent girls who are trying to conceive or are not using effective and consistent contraception because of the potential for teratogenicity with fetal exposure to efavirenz in the first trimester.

Contraceptive-Antiretroviral Drug Interactions

Several PI and NNRTI drugs are known to interact with oral contraceptives, resulting in possible decreases in ethinyl estradiol or increases in estradiol or norethindrone levels (see the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents)*** available at **http://aidsinfo.nih.gov** *[6]*. These changes may decrease the effectiveness of the oral contraceptives or potentially increase the risk of estrogen- or progestin-related side effects. Providers should be aware of these drug interactions and an alternative or additional contraceptive method should be considered in cases in which there are documented interactions. It is unknown whether the contraceptive effectiveness of progestogen-only injectable contraceptives (such as depot methoxyprogesterone acetate [DMPA]) would be compromised because these methods produce higher blood hormone levels than other progestogen-only oral contraceptives and combined oral contraceptives. In one study, the efficacy of DMPA was not altered among women receiving concomitant nelfinavir-, efavirenz-, or nevirapine-based treatment, with no evidence of ovulation during concomitant administration for 3 months, no additional side effects, and no clinically significant changes in antiretroviral drug levels *[7-8]*. There is minimal information about drug interactions with use of newer hormonal contraceptive methods (e.g., patch, vaginal ring). Adolescents who express a desire to become pregnant should be referred for preconception counseling and care, including discussion of special considerations with antiretroviral therapy use during pregnancy (see Health and Human Services [HHS] ***Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*** available at **http://aidsinfo.nih.gov** *[9]*).

Pregnant Adolescents

Pregnancy should not preclude the use of optimal therapeutic regimens. However, because of considerations related to prevention of mother-to-child transmission and to maternal and fetal safety, timing of initiation of treatment and selection of regimens may be different for pregnant women than for nonpregnant adults or adolescents. Details regarding choice of antiretroviral regimen in pregnant HIV-infected women, including adolescents, are provided in HHS ***Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*** available at **http://aidsinfo.nih.gov** *[9]*.

TRANSITION OF ADOLESCENTS INTO ADULT HIV CARE SETTINGS

Facilitating a smooth transition for adolescents with any chronic health condition from the child or adolescent health system to one devoted to the care of adults can be difficult and is especially so for adolescents infected with HIV. Transition is described as “a multifaceted, active process that attends to the medical, psychosocial,

and educational or vocational needs of adolescents as they move from the child-focused to the adult-focused health-care system" *[10]*. HIV care models for children and perinatally infected adolescents tend to be family centered, with input from members of a multidisciplinary team that often includes pediatric or adolescent physicians, nurses, social workers, and mental health professionals. These providers generally have long-standing relationships with patients and their families, and care is rendered in discreet, more intimate settings. Although expert care is also provided in the adult HIV care medical model, the adolescent may feel unfamiliar with the more individual-centered, busier clinics typical of adult medical providers and uncomfortable with providers who often do not have a long-standing relationship with the adolescent. Providing support and guidance to the adolescent and to the adult medical care provider as to what is expected from each may be helpful. Some general guidelines about transitional plans and who might best benefit from them are available *[11-12]*. Pediatric and adolescent programs may benefit from the establishment of formal programs to introduce adolescents to the adult care setting.

Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents (Updated August 16, 2010)

Panel's Recommendations:

- ***Strategies to maximize adherence should be discussed prior to initiation of antiretroviral therapy and again when changing regimens (AIII).***
- ***Adherence to therapy must be stressed at each visit, along with continued exploration of strategies to maintain and/or improve adherence (AIII).***
- ***At least one method of measuring adherence to antiretroviral therapy (e.g., quantitative and/or qualitative self-report, pharmacy refill checks, pill counts) should be used in addition to monitoring viral load (AII).***
- ***When feasible, once-daily antiretroviral regimens should be prescribed (AI*).***
- ***Maintain a nonjudgmental attitude, establish trust, and identify mutually acceptable goals for care (AII*).***

BACKGROUND

Medication adherence is fundamental to successful antiretroviral therapy. Adherence is a major factor in determining the degree of viral suppression achieved in response to antiretroviral therapy *[1-4]*. Poor adherence can lead to virologic failure. Prospective adult and pediatric studies have shown the risk of virologic failure to increase as the proportion of missed doses increases *[2, 5-7]*. Subtherapeutic antiretroviral drug levels resulting from poor adherence may facilitate the development of drug resistance to one or more drugs in a given regimen as well as possible cross resistance to other drugs in the same class. Therefore, in addition to compromising the efficacy of the current regimen, suboptimal adherence has implications for limiting future effective drug regimens for patients who develop drug-resistant viral strains.

Evidence indicates that adherence problems occur frequently in children and adolescents. Multiple studies have reported that fewer than 50% of children and/or caretakers reported full adherence to their regimens. Rates of adherence varied with method of ascertainment (parent/child report, pharmacy records), antiretroviral regimens, and study characteristics *[3-4, 8-11]*. A variety of factors, including medication formulation, frequency of dosing, child age, and psychosocial characteristics of the child and parent, have been associated with adherence, but no clear predictors of either good or poor adherence in children have been consistently identified *[7-8, 10, 12-16]*. These findings illustrate the difficulty of maintaining high levels of adherence and underscore the need to work in partnership with families to make adherence education, support, and assessment integral components of care.

SPECIFIC ADHERENCE ISSUES IN CHILDREN

Adherence is a complex health behavior that is influenced by the regimen prescribed, patient factors, and characteristics of health care providers *[14-15]*. Limited availability of palatable formulations for young children is especially problematic *[5, 17]*. Furthermore, infants and children are dependent on others for administration of medication; thus, assessment of the capacity for adherence to a complex multidrug regimen requires evaluation of the caregivers and their environments as well as the ability and willingness of the child to take the drug. Barriers faced by adult caregivers that can contribute to nonadherence in children include forgetting doses, changes in routine, being too busy, and child refusal *[18]*. Some caregivers may place too much responsibility on older children for managing medications before they are developmentally able to take on such tasks *[19]*. Many other barriers to adherence exist for children with HIV infection. For example, caregivers' unwillingness to disclose the child's HIV infection status to others may create specific problems, including reluctance of caregivers to fill prescriptions locally, hiding or relabeling medications to maintain

secrecy within the household, reduction of social support, and a tendency to skip doses when the parent is away from the home or when the child is at school.

SPECIFIC ADHERENCE ISSUES FOR ADOLESCENTS

HIV-infected adolescents also face specific adherence challenges *[7, 20-22]*. Several studies have identified pill burden as well as lifestyle issues (not carrying medication, change in schedule) as barriers to complete adherence *[7, 20]*. Denial and fear of their HIV infection is common, especially in recently diagnosed youth; this may lead to refusal to initiate or continue antiretroviral therapy. Distrust of the medical establishment, misinformation about HIV, and a lack of knowledge about the availability and effectiveness of antiretroviral treatments can all be barriers to linking adolescents to care and maintaining successful antiretroviral therapy. Perinatally infected youth are familiar with the challenges of taking complex drug regimens and with the routine of chronic medical care; nevertheless, they may have long histories of inadequate adherence. Regimen fatigue has also been identified as a barrier to adherence in adolescents *[23]*. Regardless of the mode of acquisition of HIV infection, HIV-infected adolescents may suffer from low self-esteem, may have unstructured and chaotic lifestyles and concomitant mental illnesses, or may cope poorly with their illness due to a lack of familial and social support. Depression, alcohol or substance abuse, poor school attendance, and advanced HIV disease stage all correlate with nonadherence *[21, 24]*. In a study of 833 HIV-infected Medicaid beneficiaries age 12–17 years, youth diagnosed with a psychiatric comorbidity (substance abuse, conduct disorder, or emotional disorder) were less likely to be receiving combination therapy; however, for those on therapy, only a conduct disorder diagnosis was associated with lower adherence *[25]*. A review of published papers on adherence among HIV-infected youth, however, suggests that depression and anxiety have been consistently associated with poorer adherence *[24]*. Adherence to complex regimens is particularly challenging at a time of life when adolescents do not want to be different from their peers. Further difficulties face adolescents who live with parents or partners to whom they have not yet disclosed their HIV status and those who are homeless and have no place to store medicine. Treatment regimens for adolescents must balance the goal of prescribing a maximally potent antiretroviral regimen with realistic assessment of existing and potential support systems to facilitate adherence.

Interventions to promote long-term adherence to antiretroviral treatment have not been rigorously evaluated in adolescents. In clinical practice, reminder systems, such as beepers and alarm devices, are well accepted by some youth. Small, discreet pillboxes in which to store medications in an organized fashion may be useful *[26]*. In a pilot study evaluating peer support and pager messaging in an adult population, peer support was associated with greater self-reported adherence post intervention but the effect was not sustained at follow-up. Pager messaging was not associated with reported adherence but improved biologic outcomes were measured *[27]*. Another study evaluating the efficacy of a 4-session, individual, clinic-based motivational interviewing intervention targeting multiple risk behaviors in HIV-infected youth demonstrated an association with lower viral load at 6 months among youth taking antiretroviral therapy at 6 months. However, reduction in viral load was not maintained at 9 months *[28]*.

ADHERENCE ASSESSMENT AND MONITORING

The process of adherence preparation and assessment should begin before therapy is initiated or changed, and a routine adherence assessment should be incorporated into every clinic visit. A comprehensive assessment should be instituted for all children in whom antiretroviral treatment initiation or change is considered. Evaluations should include nursing, social, and behavioral assessments of factors that may affect adherence by the child and family and can be used to identify individual needs for intervention. Adherence preparation should focus on establishing a dialogue and a partnership in medication management. Specific, open-ended questions should be used to elicit information about past experience as well as concerns and expectations about treatment. When assessing readiness and preparing to begin treatment, it is important to obtain explicit agreement with the treatment plan, including strategies to support adherence.

Adherence is difficult to assess accurately; different methods of assessment have been shown to yield different results, and each approach has limitations *[29-31]*. Both caregivers and health care providers often

overestimate adherence. Use of multiple methods to assess adherence is recommended. Viral load response to a new regimen is often the most accurate indication of adherence, but it may be a less valuable measure in children with long treatment histories and multidrug-resistant virus. Other measures include quantitative self-report of missed doses by caregivers and children or adolescents (focusing on recent missed doses during a 3-day or 1-week period), descriptions of the medication regimens, and reports of barriers to administration of medications. Caregivers may report number of doses taken more accurately than doses missed *[32]*. Also, targeted questions about stress, pill burden, and daily routine are recommended *[7-8, 29]*. Pharmacy refill checks and pill counts can identify adherence problems not evident from self-reports *[33]*. Electronic monitoring devices, such as Medication Event Monitoring System (MEMS) caps, which record opening of medication bottles on a computer chip in the cap *[34]*, have been shown to be useful tools to measure adherence in some settings *[33, 35-36]*. Home visits can play an important role in assessing adherence and, in some cases, suspected nonadherence is confirmed only when dramatic clinical responses to antiretroviral therapy occur during hospitalizations or in other supervised settings *[37-40]*. Preliminary studies suggest that monitoring plasma concentrations of PIs, or therapeutic drug monitoring, may be a useful method to identify nonadherence *[41]*.

It is important for clinicians to recognize that nonadherence is a common problem and that it can be difficult for patients to share information about missed doses or difficulties adhering to treatment. Furthermore, adherence can change over time. An adolescent who was able to strictly adhere to treatment upon initiation of a regimen may not be able to maintain complete adherence over time. A nonjudgmental attitude and trusting relationship foster open communication and facilitate assessment. To obtain information on adherence in older children, it is often helpful to ask both the HIV-infected child and caregivers about missed doses and problems. Their reports may differ significantly; therefore, clinical judgment is required to best interpret adherence information obtained from the multiple sources *[42-43]*.

STRATEGIES TO IMPROVE AND SUPPORT ADHERENCE

Intensive follow-up is required, particularly during the critical first few months after therapy is started; patients should be seen frequently to assess adherence and determine the need for strategies to improve and support adherence. Strategies include development of patient-focused treatment plans to accommodate specific patient needs, integration of medication administration into the daily routines of life (e.g., associating medication administration with daily activities such as brushing teeth), and use of social and community support services. Multifaceted approaches that include regimen-related strategies; educational, behavioral, and supportive strategies focused on children and families; and strategies that focus on health care providers—rather than one specific intervention—may be most effective *[44-47]*. Although quite labor intensive, programs designed to administer directly observed combination therapy to adults in either the clinic or at home have demonstrated successful results in both the United States and in international, resource-poor settings *[48-52]*. In particular, modified directly observed therapy (m-DOT) when one dose is administered in a supervised setting and the remaining portions are self-administered appears to be both feasible and acceptable *[47]*. **Table 16** summarizes some of the strategies that can be used to support and improve adherence to antiretroviral medications.

Regimen-Related Strategies

Highly active antiretroviral regimens often require the administration of large numbers of pills or unpalatable liquids, each with potential side effects and drug interactions, in multiple daily doses. To the extent possible, regimens should be simplified with respect to the number of pills or volume of liquid prescribed, as well as frequency of therapy, and chosen to minimize drug interactions and side effects *[53]*. When nonadherence is a problem, addressing medication-related issues, such as side effects, may result in improvement. If a regimen is overly complex, it may be simplified. For example, when the burden of pills is great, one or more drugs can be changed to result in a regimen containing fewer pills and potentially greater adherence. Several studies in adults have demonstrated better adherence in once-daily compared with twice-daily antiretroviral regimens *[54-56]*. When nonadherence is related to poor palatability of a liquid formulation or crushed pills, the offending taste may be masked by a small amount of flavoring syrups or food, as long as the medication is not

one with contraindications to simultaneous administration of food (see **Appendix B: Pediatric Antiretroviral Drug Information**), or the child may be taught to swallow pills in order to overcome medication aversion *[57]*.

Child/Family-Related Strategies

The primary approach taken by the clinical team to promote medication adherence in children is patient/caregiver education. Educating families about adherence should begin before antiretroviral medications are initiated or changed and should include a discussion of the goals of therapy, the reasons for making adherence a priority, and the specific plans for supporting and maintaining the child's medication adherence. Caregivers should understand that the first antiretroviral regimen has the best chance of long-term success. Caregiver adherence education strategies should include the provision of both information and adherence tools, such as written and visual materials; a daily schedule illustrating times and doses of medications; and demonstration of the use of syringes, medication cups, and pillboxes.

A number of behavioral tools can be used to integrate taking medications into the HIV-infected child's daily routine. The use of behavior modification techniques, especially the application of positive reinforcements and the use of small incentives for taking medications, can be effective tools to promote adherence *[58-60]*. Training children on swallowing pills has been associated with improved adherence at 6 months post-training in a small study of children age 4 to 21 *[61]*. Availability of mental health services and treatment of mental health disorders may also facilitate adherence to complex antiretroviral regimens. For nonadherent children who are at risk of disease progression and for whom aversion to taking medications is severe and persistent, a gastrostomy tube may be considered *[62]*. Home nursing interventions may also be beneficial where adequate resources are available *[63]*. Directly observed dosing of antiretroviral medications has been implemented in adults and pediatrics with promising results *[48-52, 64]*, and such an approach has been implemented in some pediatric HIV programs, using home nursing services as well as daily medication administration in the clinic setting. Other strategies to support adherence that have been employed in the clinical setting include setting patient cell phones to alarm when medications are due to be taken, providing pill boxes and other adherence support tools, and weekly filling of pill boxes by nursing or pharmacy staff particularly for patients with complex regimens.

Health Care Provider-Related Strategies

Providers have the ability to improve adherence through their relationships with the families. This process begins early in the provider's relationship with the family, when the clinician obtains explicit agreement about the medication and treatment plan and any further strategies to support adherence. Fostering a trusting relationship and engaging in open communication are particularly important *[65-67]*. Provider characteristics that have been associated with improved patient adherence in adults include consistency, giving information, asking questions, technical expertise, and commitment to follow-up. Creating an environment in the health care setting that is child centered and includes caregivers in adherence support has also been shown to improve treatment outcomes *[68]*.

Table 16. Strategies to Improve Adherence with Antiretroviral Medications

Initial Intervention Strategies
• Establish trust and identify mutually acceptable goals for care. • Obtain explicit agreement on need for treatment and adherence. • Identify depression, low self-esteem, drug use, or other mental health issues for the child/adolescent and/or caregiver that may decrease adherence. Treat prior to starting antiretroviral drugs, if possible. • Identify family, friends, health team members, or others who can help with adherence support. • Educate patient and family about the critical role of adherence in therapy outcome. • Specify the adherence target: ≥95% of prescribed doses. • Educate patient and family about the relationship between partial adherence and resistance. • Educate patient and family about resistance and constraint of later choices of antiretroviral drug (i.e., explain that although a failure of adherence may be temporary, the effects on treatment choice may be permanent). • Develop a treatment plan that the patient and family understand and to which they feel committed. • Establish readiness to take medication by practice sessions or other means. • Consider a brief period of hospitalization at start of therapy in selected circumstances for patient education and to assess tolerability of medications chosen.
Medication Strategies
• Choose the simplest regimen possible, reducing dosing frequency and number of pills. • Choose a regimen with dosing requirements that best conform to the daily and weekly routines and variations in patient and family activities. • Choose the most palatable medicine possible (pharmacists may be able to add syrups or flavoring agents to increase palatability). • Choose drugs with the fewest side effects; provide anticipatory guidance for management of side effects. • Simplify food requirements for medication administration. • Prescribe drugs carefully to avoid adverse drug-drug interactions. • Assess pill swallowing capacity and offer pill swallowing training.
Follow-up Intervention Strategies
• Monitor adherence at each visit and in between visits by telephone or letter as needed. • Provide ongoing support, encouragement, and understanding of the difficulties of the demands of attaining ≥95% adherence with medication doses. • Use patient education aids including pictures, calendars, and stickers. • Use pill boxes, reminders, alarms, pagers, and timers. • Provide follow-up clinic visits or telephone calls to support and assess adherence. • Provide access to support groups, peer groups, or one-on-one counseling for caregivers and patients, especially for those with known depression or drug use issues that are known to decrease adherence. • Provide pharmacist-based adherence support. • Consider gastrostomy tube use in selected circumstances. • Consider a brief period of hospitalization for selected circumstances of apparent virologic failure to assess adherence and reinforce that medication adherence is fundamental to successful antiretroviral therapy. • Consider directly observed therapy at home, in the clinic, or during a brief inpatient hospitalization.

Management of Medication Toxicity or Intolerance (Updated August 16, 2010)

Panel's Recommendations:

- ***If a child has severe or life-threatening toxicity, all components of the drug regimen should be stopped immediately (AIII). Once the symptoms of toxicity have resolved, antiretroviral therapy should be resumed with substitution of a different antiretroviral drug or drugs for the offending agent(s) (AII*).***
- ***When changing therapy because of toxicity or intolerance to a specific drug in a virally suppressed individual, changing a single drug in a multi-drug regimen is permissible; if possible, an agent with a different toxicity and side effect profile should be chosen (AI*).***
- ***The toxicity and the medication presumed responsible should be documented in the medical record and the caregiver and patient advised of the drug-related toxicity to facilitate future medication choices if care is transferred (AIII).***
- ***Dose reduction is not a recommended option in the setting of antiretroviral toxicity except when therapeutic drug monitoring indicates a drug concentration above the normal therapeutic range (AII*).***

Side effects or intolerance of antiretroviral agents occur with moderate frequency and should prompt a re-evaluation of the antiretroviral regimen. Drug-related toxicity may be acute, occurring soon after a drug has been administered; subacute, occurring within 1−2 days of administration; or late, occurring after prolonged drug administration. Such adverse events may vary in severity from mild to severe and life threatening (see **Tables 17a–17h. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations**).

Identification of the responsible agent may allow for substitution of a similar agent to which the patient's virus is sensitive. Knowledge of the patient's prior antiretroviral history and, if possible, viral resistance profile prior to the current course of antiretroviral therapy is essential. Any new agent used should be assessed for likely effectiveness against the patient's virus and for possible interactions with the other medications the patient will take.

Experience with antiretroviral drugs has led to the recognition of several types of distinct adverse drug effects that may be most common with certain antiretroviral drugs or drug classes (see **Tables 17a–17h. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations**).

The physician, patient, and caregiver should discuss the response to a medication-related toxicity, taking into account the severity of toxicity, the relative need for viral suppression, and the available antiretroviral options. In general, mild and moderate toxicities do not require discontinuation of therapy or drug substitution; symptomatic treatment may be given, such as antihistamines for a mild rash. For some moderate toxicities, substituting the toxicity-associated antiretroviral drug with a drug in the same drug class but with a different toxicity profile may be sufficient and discontinuation of all therapy may not be required. Severe, life-threatening toxicity requires discontinuation of all antiretroviral drugs and the initiation of appropriate supportive therapy (depending on the type of toxicity). Another drug can be substituted for the drug associated with the toxicity once the patient is stabilized and the toxicity is resolved.

When a patient experiences an unacceptable adverse effect from antiretroviral therapy every attempt should be made to identify the offending agent and replace the drug with another effective agent to minimize the amount of time a patient is on suboptimal therapy. For example, if therapy needs to be stopped due to a severe or life-threatening side effect, all antiretroviral drugs should be stopped. Once the offending drug or alternative cause for the adverse event has been determined, planning can begin for resumption of therapy with a new antiretroviral drug regimen that does not contain the offending drug or with the original regimen if the event is attributable to another cause. All drugs in the antiretroviral regimen should then be started simultaneously, rather than starting them one at a time and observing for adverse effects. Many experts recommend stopping

efavirenz or nevirapine several days before stopping other drugs, if possible, because these drugs have a significantly longer half-life than NRTI antiretroviral drugs. However, if a patient has a severe or life-threatening toxicity, all components of the drug regimen should be stopped simultaneously, regardless of drug half-life.

When therapy is changed because of toxicity or intolerance in the context of virologic suppression, agents with different toxicity and side-effect profiles should be chosen, when possible. Clinicians should have comprehensive knowledge of the toxicity profile of each agent before selecting a new regimen. In the event of drug intolerance, changing a single drug in a multi-drug regimen is a permissible option. For a patient who is not virally suppressed, a single drug substitution with an active agent is generally not recommended due to concern for development of resistance (see **Approach to the Management of Antiretroviral Treatment Failure**).

Therapeutic drug monitoring (TDM) is not available on a routine basis to most clinicians, and the settings in which TDM is useful are unclear, especially in children. One such setting, however, may be in the context of a child with mild or moderate toxicity possibly attributable to a particular antiretroviral agent (see **Role of Therapeutic Drug Monitoring in Management of Treatment Failure**). In this situation, it is reasonable for the clinician to use TDM (if available) to determine if the toxicity is due to a concentration of drug exceeding the normal therapeutic range. This is the only setting in which dose reduction would be considered appropriate management of drug toxicity, and even then it should be used with caution.

Management strategies for drug intolerance include:

- Symptomatic treatment of mild-to-moderate transient side effects.
- If necessary, change from one drug to another drug to which the patient's virus is sensitive (e.g., change to stavudine for zidovudine-related anemia or to nevirapine for efavirenz-related central nervous system symptoms).
- Change in drug class, if necessary (e.g., from a PI to an NNRTI or vice versa) and if the patient's virus is sensitive to a drug in that class.
- Dose reduction only when drug levels are determined excessive.

Tables 17a–17h. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations describe specific adverse drug effects observed in children, including lactic acidosis, hepatic toxicity, fat maldistribution and body habitus changes, hyperlipidemia, hyperglycemia, osteopenia, hematological complications, and hypersensitivity reactions and skin rashes. The tables include information on common causative drugs, estimated frequency of occurrence, timing of symptoms, risk factors, potential preventive measures, and suggested clinical management strategies and provide selected references regarding these toxicities in pediatric patients.

Table 17a. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Hematologic Effects

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Hematologic Effects:						
Anemia*	Principally ZDV	Onset: Variable, weeks to months Presentation: • Most commonly asymptomatic or mild fatigue, pallor, tachypnea • Rarely, congestive heart failure	HIV-exposed newborns: • Uncommon but coincident with physiologic Hgb nadir HIV-infected children on ARVs: • 2–3 times more common with ZDV-containing regimens • Less frequent in recent studies, possibly due to lower dosing of ZDV	HIV-exposed newborns: • Premature birth • *In utero* exposure to ARVs • Advanced maternal HIV disease • Neonatal blood loss HIV-infected children on ARVs: • Underlying hemoglobinopathy (sickle cell disease, G6PD deficiency) • Poorly controlled HIV • Marrow-toxic drugs (e.g., trimethoprim-sulfamethoxazole, rifabutin) • Iron deficiency	HIV-exposed newborns: • Monitor CBC at birth. • Consider repeat CBC at 4 weeks for higher risk babies (exposed to ARVs *in utero* or as neonates, premature birth, or low birth Hgb). HIV-infected children on ARVs: • Avoid ZDV in children with anemia when alternative agents are available. • Monitor CBC 3–4 times per year as part of routine care.	HIV-exposed newborns: • Rarely require intervention unless Hgb is <7.0 gm/dL or anemia is associated with symptoms. • Consider discontinuing ZDV if ≥4 weeks of 6-week ZDV prophylaxis regimen are already completed. (see **Perinatal Guidelines**†). HIV-infected children on ARVs: • Discontinue non-ARV marrow-toxic drugs if feasible. • Treat coexisting iron deficiency, OIs, malignancies. • Rarely necessary to discontinue ARV therapy. • For persistent anemia thought to be associated with ARVs: o change to a non-ZDV-containing regimen; o give erythropoietin 50–200 IU/kg/dose 3 times weekly.

Table 17a. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Hematologic Effects

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Neutropenia*	Principally ZDV	Onset: Variable Presentation: • Most commonly asymptomatic with ANC >500 cells/mm^3 • Associated with increased bacterial infections if ANC persistently <500 cells/mm^3	HIV-exposed newborns: • Rare HIV-infected children on ARVs: • 9.9%–26.8% of children on ARVs, depending upon the ARV regimen • Higher with ZDV-containing regimens	HIV-exposed newborns: • *In utero* exposure to ARVs HIV-infected children on ARVs: • Poorly controlled HIV infection • Marrow-toxic drugs (e.g., trimethoprim-sulfamethoxazole, ganciclovir, hydroxyurea, rifabutin)	HIV-infected children on ARVs: • Monitor CBC 3–4 times per year as part of routine care.	HIV-infected children on ARVs: • Intervention typically not necessary unless ANC <500 cells/mm^3 for prolonged periods or if associated with recurrent infections. • Discontinue non-ARV marrow-toxic drugs if feasible. • Treat coexisting OIs, malignancies. • Rarely necessary to discontinue ARV therapy. • For persistent neutropenia thought to be associated with ARVs: o change to a non-ZDV-containing regimen o give G-CSF 5–10 mcg/kg once daily (doses up to 20 mcg/kg have been used).

* HIV infection itself, opportunistic infections, and medications used to prevent OIs, such as trimethroprim-sulfamethoxazole, may all contribute to anemia, neutropenia, and thrombocytopenia.

† Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States

Key to Abbreviations: ANC = absolute neutrophil count; ARVs = antiretrovirals; CBC = complete blood count; G6PD = glucose-6-phosphate dehydrogenase; G-CSF = granulocyte colony-stimulating factor; Hgb = hemoglobin; IU = International Unit; OIs = opportunistic infections; ZDV = zidovudine

Table 17b. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Hepatic Events

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Hepatic Events:						
Hepatic toxicity (elevated AST, ALT, clinical hepatitis)	All ARVs	Onset: • *NNRTI and PI therapy*: Within 12 weeks of initiation. • *NRTI therapy*: Within months to years of initiation. • *Any antiretroviral combination regimen*: Early due to immune reconstitution inflammatory syndrome. Presentation: • Asymptomatic elevation of AST, ALT. • May be associated with symptoms of clinical hepatitis including nausea, fatigue, and jaundice. • NRTIs, especially ZDV, ddI, d4T, may be associated with lactic acidosis and hepatic steatosis. • Rarely, prolonged exposure to ddI is associated with non-cirrhotic portal hypertension with esophageal varicies.	• Uncommon in children. • Frequency varies with different agents and drug combinations (NVP, TPV of particular concern).	• HBV or HCV coinfection • Elevated baseline ALT, AST • Other hepatotoxic medications • Alcohol use • Underlying liver disease • For NVP-associated hepatic events in adults: o female with pre-NVP CD4 >250 cells/mm^3 o male with pre-NVP CD4 >400 cells/mm^3 • Higher drug concentrations for PIs, particularly TPV	Prevention: Avoid concomitant use of hepatotoxic medications. Monitoring: *For ARVs other than NVP*: Obtain AST, ALT at baseline and at least every 3–4 months or more frequently in at-risk patients (e.g., HBV or HCV coinfected, elevated baseline AST, ALT). *For NVP*: Obtain AST, ALT at baseline, at 2 and 4 weeks, then every 3 months.	• In asymptomatic patients with ALT or AST >5–10 times ULN, some may consider discontinuing ARVs, others may continue therapy with close monitoring. • If hepatic enzymes elevated >5–10 times ULN, most clinicians would avoid NVP. • In symptomatic patients, discontinue all ARVs and other potential hepatotoxic agents and avoid restart of the offending agent. • If a symptomatic hepatic event occurs on NVP, permanently discontinue NVP (see also NVP hypersensitivity). • When clinical hepatitis is associated with lactic acidosis, avoid restart of the most likely agent, NRTIs, ZDV, d4T,

Table 17b. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Hepatic Events

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
		• AST, ALT elevations while on NVP or ABC may be associated with a hypersensitivity reaction. • HBV-coinfected patients may develop severe hepatic flare with initiation, withdrawal, or when resistance develops with 3TC, FTC, TDF.				ddI in particular (see also lactic acidosis). • Rule out coinfection with HAV, HBV, HCV, EBV, and CMV.
Indirect hyperbilirubinemia	IDV, ATV	Onset: Early in therapy. Presentation: • Jaundice. • Asymptomatic elevation of indirect bilirubin levels.	HIV-infected children receiving ATV: 49% developed increased total bilirubin levels (≥3.2 mg/dL); 13% had jaundice/scleral icterus.	Not associated with HBV or HCV.	Monitoring: Assess bilirubin levels periodically, especially in first few months on regimen.	Not necessary to discontinue the offending agent except for cosmetic reasons (hyperbilirubinemia may improve over time).

Key to Abbreviations: 3TC = lamivudine; ABC = abacavir; ALT = alanine transaminase; ARVs = antiretrovirals; AST = aspartate aminotransferase; ATV = atazanavir; CMV = cytomegalovirus; d4T = stavudine; ddI = didanosine; EBV = Epstein-Barr virus; FTC = emtricitabine; HAV = hepatitis A virus; HBV = hepatitis B virus; HCV = hepatitis C virus; IDV = indinavir; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; NVP = nevirapine; PI = protease inhibitor; TDF = tenofovir disoproxil fumarate; TPV = tipranavir; ULN = upper limit of normal; ZDV = zidovudine

Table 17c. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Insulin Resistance, Asymptomatic Hyperglycemia, Diabetes Mellitus

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Insulin resistance, asymptomatic hyperglycemia, diabetes mellitus (DM)*	• Thymidine analogue NRTIs (d4T > ZDV) • Some PIs but unclear if class effect	Onset: Weeks to months after beginning therapy; median = 60 days (adult data) Presentation: • *Most commonly*: Asymptomatic fasting hyperglycemia, possibly in the setting of lipodystrophy, metabolic syndrome, or growth delay • *Also possible*: Frank DM (polyuria, polydipsia, polyphagia, fatigue, hyperglycemia)	Impaired fasting glucose: • *ARV-treated adults*: 3%–25% • *ARV-treated children*: 0%–7% Impaired glucose tolerance: • *ARV-treated adults*: 16%–35% • *ARV-treated children*: 3%–4% DM: • *ARV-treated adults*: 1.2–4.7 per 100 person-years (2–4-fold greater than that for non-HIV-infected adults) • *ARV-treated children*: Very rare in HIV-infected children	Risk factors for Type 2 DM: • Lipodystrophy, metabolic syndrome • Family history of DM • Overweight, obesity	Prevention: • Lifestyle modification (see Management). • Although uncertain, avoiding use of d4T, PI-containing regimens might reduce risk. Monitoring: • Monitor for polydipsia, polyuria, polyphagia, change in body habitus, acanthosis nigricans. • Obtain random plasma glucose (RPG) levels at: o initiation of ARV therapy; o 3–6 months later; and o annually thereafter. • For RPG ≥140 mg/dL, obtain fasting plasma glucose (FPG) performed after 8-hour fast and consider referral to endocrinologist.	• Counsel lifestyle modification (low fat diet, exercise, no smoking). • Consider changing from thymidine analogue NRTI (d4T or ZDV)-containing regimen. • *For either RPG ≥200 mg/dL plus symptoms of DM or FPG ≥126 mg/dL*: Diagnostic criteria for DM are met; consult endocrinologist. • *FPG 100–125 mg/dL*: Impaired FPG is suggestive of insulin resistance; consult endocrinologist. • *FPG <100 mg/dL*: Suggests no current insulin resistance; recheck in 6–12 months.

***** Insulin resistance, asymptomatic hyperglycemia, and diabetes mellitus form a spectrum of increasing severity. *Insulin resistance* is often defined as elevated insulin levels for the level of glucose observed; *impaired fasting plasma glucose* (impaired FPG) as an FPG of 100–125 mg/dL; *impaired glucose tolerance* is an elevated 2-hour PG of 140–199 mg/dL in a standard oral glucose tolerance test (OGTT); and *diabetes mellitus* as either a FPG ≥126 mg/dL, a random PG ≥200 mg/dL in a patient with hyperglycemia symptoms, a HgbA1C of ≥6.5%, or a 2-hour PG after OGTT ≥200 mg/dL. However, the Panel does not recommend routine determinations of insulin levels, glycosylated hemoglobin A1C, or glucose tolerance without consultation with an endocrinologist; these guidelines are instead based on the readily available random and fasting plasma glucose levels.

Key to Abbreviations: ARV = antiretroviral; d4T = stavudine; DM = diabetes mellitus; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; ZDV = zidovudine

Table 17d. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Dyslipidemia

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/Monitoring	Management
Dyslipidemia	PIs: All PIs; lower incidence with ATV NRTIs: Especially d4T	Onset: Weeks to months after beginning therapy Presentation: *PIs*: ↑LDL-C, TC, and TG *NNRTIs*: ↑LDL-C, TC, and HDL-C *NRTIs*: ↑LDL-C, TC, and TG	20%–50% of children receiving combination antiretroviral therapy will have lipoprotein abnormalities.	• HIV infection • Poor diet • Lack of exercise • Obesity • Hypertension • Smoking • Family history of dyslipidemia or premature CVD • Metabolic syndrome	Prevention: Low fat diet, exercise, no smoking. Monitoring: *Adolescents and adults*: Obtain fasting (12-hour) TC, HDL-C, TG, LDL-C prior to initiating or changing ARV therapy, 3–6 months thereafter, then every 6–12 months. *Children without lipid abnormalities or risk factors*: Obtain nonfasting screening lipid profiles prior to initiating or changing therapy and every 6–12 months if stable. If TG or LDL-C is elevated, obtain fasting blood tests. *Children with lipid abnormalities and/or additional risk factors*: Obtain fasting (12-hour) TC, HDL-C, TG, LDL-C prior to initiating or changing therapy and every 6 months (or more often if indicated). *Children receiving lipid-lowering therapy with statins or fibrates*: Obtain fasting (12-hour) lipid profiles, liver function tests (LFTs), and creatine kinase (CK) prior to initiating lipid therapy and at 4 weeks and 8 weeks after starting lipid therapy. If minimal	• Counsel lifestyle modification (low fat diet, exercise, smoking cessation) for adequate trial period (3–6 months). • Switch to a new ARV regimen less likely to cause lipid abnormalities.* Pharmacologic Management: • Prompt intervention is required in patients with TG ≥500 mg/dL (high risk of pancreatitis). • Statins such as pravastatin or atorvastatin† • Fibrates such as gemfibrozil and fenofibrate may be used as alternative agents for adults with ↑TG but are not approved for use in children. • N-3 polyunsaturated fatty acids (PUFAs) derived from fish oils • No consensus as to what LDL-C should prompt treatment in children receiving ARVs ‡ o *High-risk patients*:

Table 17d. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Dyslipidemia

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/Monitoring	Management
					alterations in AST, ALT, and CK, then every 3 months. Whenever doses of antihyperlipidemic agents are increased, repeat at 4 weeks.	Goal LDL-C ≤100 mg/dL o *Moderate-risk patients*: Goal LDL-C ≤130 mg/dL o *At-risk patients*: Goal LDL-C ≤160 mg/dL.

[*] The risks of new treatment-related toxicities and virologic failure that could occur with changes in therapy must be weighed against the potential risk of drug interactions and toxicities associated with the use of lipid-lowering agents.

[†]Statins are teratogenic and should not be used in female patients who may become pregnant. Serious toxicities include hepatotoxicity, skeletal muscle toxicity, and rhabdomyolysis. Experience with statins limited to children >6 years of age. Multiple drug interactions with lipid-lowering agents and ARVs.

Pravastatin (Pravachol)
8–13 years of age: 20 mg once daily; 14–18 years of age: 40 mg once daily

Atorvastatin (Lipitor)
>6 years of age: 10–20 mg once daily

[‡]It is unclear what the long-term risks of lipid abnormalities are in children receiving combination antiretroviral therapy. However, persistent dyslipidemia in children is likely to lead to premature cardiovascular disease.

Key to Abbreviations: ALT = alanine transaminase; ARV = antiretroviral; AST = aspartate aminotransferase; CVD = cardiovascular disease; d4T = stavudine; HDL-C = high-density lipoprotein cholesterol; LDL-C = low density lipoprotein cholesterol; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; TC = total cholesterol; TG = triglycerides; ZDV = zidovudine

Table 17e. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Skin Rash, SJS/EM/TEN, HSR

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Skin rash	NVP, EFV, ETR, FPV, ATV, FTC ABC, DRV, TPV, TDF, LPV/r, RAL, MVC	Onset: The first few days to weeks after starting therapy. Presentation: Most rashes are mild-to-moderate, diffuse maculopapular eruptions. Some rashes are a manifestation of systemic hypersensitivity (see also hypersensitivity reaction).	Common (>10% adults and/or children): NVP, EFV, ETR, FPV, ATV, FTC Less common (5%–10%): ABC, DRV, TPV, TDF Unusual (2%–4%): LPV/r, RAL, MVC	• Rash with a sulfonamide is a risk factor for rash with NNRTIs and the PIs containing a sulfonamide moiety (FPV, APV, DRV, TPV). • Possible association of the HLA-DRB 101 allele with rash with NVP or EFV.	When starting NVP or restarting after interruptions ≥7 days: • Once-daily dosing for 2 weeks (50% of total daily dose), then escalation to target dose with twice-daily dosing is associated with fewer rashes.* • Avoid the use of corticosteroids during NVP dose escalation. • Assess patient for rash severity and presence of systemic signs and symptoms (see also hypersensitivity reaction).	Mild-to-moderate rash: • Prescribe antihistamine as needed; the antiretroviral medication can be continued.* Severe rash (accompanied by blisters, fever, involvement of the oral/anal mucous membranes, conjunctivitis, edema, arthralgias): • Discontinue all ARVs and other possible causative agents such as cotrimoxazole. Do not restart the offending medication. (See SJS/EM/TEN.) • In case of SJS/EM/TEN with one NNRTI, many experts would avoid use of other NNRTIs. • Measure hepatic transaminases if rash develops with NVP treatment. If hepatic transaminases are

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
						elevated, NVP should be discontinued and not restarted (see NVP hypersensitivity).
	ENF	Onset: The first few days to weeks after starting therapy. Presentation: Local injection site reactions with pain, erythema, induration, nodules and cysts, pruritis, ecchymosis. Often multiple reactions at the same time.	Adults: >90% (resulted in ENF discontinuation in 7%)	Unknown,	• During routine visits assess patient for local reactions. • Rotate injection sites. • Massage area after injection.	• Continue the agent as tolerated by the patient, adjust injection technique, and rotate injection sites.
Stevens-Johnson syndrome (SJS)/ erythema multiforme major (EM)/toxic epidermal necrolysis (TEN)	NVP, EFV, ETR, FPV, ABC, DRV, ZDV, ddI, IDV, LPV/r, ATV	Onset: The first few days to weeks after initiating therapy. Presentation: Skin eruption occurs with mucous membrane ulceration, conjunctivitis. Can evolve into blister/bullae formation and can progress to skin necrosis. Systemic symptoms may include fever, tachycardia, malaise, myalgia, arthralgia.	Infrequent: NVP (0.3%), EFV (0.1%), ETR (<0.1%) Case reports: FPV, ABC, DRV, ZDV, ddI, IDV, LPV/r, ATV	Adults: • Female • Black • Asian • Hispanic.	• For NVP, 2-week lead-in period for start or restart for interruptions ≥7 days with once-daily dosing then dose escalation to twice daily as recommended may prevent the rash.* • Counsel families to report symptoms as soon as they appear.	• Discontinue all ARVs and other possible causative agents such as cotrimoxazole. • May need intensive care support, intravenous hydration, aggressive wound care, pain management, antipyretics, parenteral nutrition, and antibiotics in case of superinfection. • Corticosteroids and/or IVIG are sometimes used but use of each is controversial. • Do not reintroduce the offending

Table 17e. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Skin Rash, SJS/EM/TEN, HSR

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
						medication. • In case of SJS/EM/TEN with one NNRTI, many experts would avoid use of other NNRTIs.
Systemic hypersensitivity reaction (HSR) (with or without skin involvement)	ABC	Onset: Within the first 6 weeks with first use; within hours with reintroduction. Presentation: Symptoms include high fever, diffuse skin rash, malaise, nausea, headache, myalgia, arthralgia, diarrhea, vomiting, abdominal pain, pharyngitis, respiratory symptoms such as dyspnea. Symptoms worsen to include hypertension and vascular collapse with continuation. Symptoms can mimic anaphylaxis with rechallenge.	2.3%–9% (varies by racial/ethnic group)	• HLA-B*5701 (HSR very uncommon in people who are HLA-B*5701 negative); also HLA-DR7, HLA-DQ3. • Whites are at much greater risk of HSR than blacks or Asians.	• Screen for HLA-B*5701. • ABC should not be prescribed if HLA-B*5701 is positive. The patient should be labeled as ABC allergic in the medical record. • Counsel families about the signs and symptoms of HSR to ensure prompt reporting of reactions.	• Discontinue ARVs and investigate for other causes of the symptoms such as an intercurrent viral illness. Treat symptoms as necessary. • Most symptoms resolve by 48 hours after discontinuation of ABC. • Do not rechallenge with ABC even if the patient is HLA-B*5701 negative.
	NVP	Onset: Most frequent in the first few weeks of therapy but can occur through 18 weeks. Presentation: Flu-like symptoms (including nausea, vomiting, myalgia, fatigue, fever, abdominal pain, jaundice) with or	4% (2.5%–11%)	For adults: • Treatment naïve with higher CD4 count (>250 cells/mm^3 in women; >400 cells/mm3 in men) • Females 3-fold higher risk than males • NVP	• 2-week lead-in period for start or restart for interruptions ≥7 days with once-daily dosing then dose escalation to twice daily as recommended may reduce rash and hepatic events.*	• Discontinue ARVs. • Consider other causes for hepatitis and discontinue all hepatotoxic medications. • Provide supportive care as indicated and close monitoring. • Do not reintroduce NVP. The safety of other NNRTIs is

Table 17e. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Skin Rash, SJS/EM/TEN, HSR

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
		without skin rash that may progress to hepatic failure with encephalopathy. DRESS syndrome (drug rash with eosinophilia and systemic symptoms) has also been described.		hepatoxicitiy and hypersensitivity may be less common in prepubertal children than in adults.	• Counsel families about signs and symptoms of HSR to ensure prompt reporting of reactions. • Obtain AST and ALT in patients with rash. • Obtain AST and ALT at baseline, prior to dose escalation, 2 weeks post dose escalation, and at 3-month intervals thereafter. • Avoid use in women with CD4 >250 cells/mm^3 and in men with CD4 >400 cells/mm^3 unless benefits outweigh risks. • Do not use NVP in postexposure prophylaxis.	unknown following symptomatic hepatitis due to NVP, and many experts would avoid the NNRTI drug class when restarting treatment.
	ENF	Onset: Any time during therapy. Presentation: Symptoms may include rash, fever, nausea, vomiting, rigors, hypertension, elevated hepatic transaminases.	<1%	Unknown.	• Evaluate for hypersensitivity if the patient is symptomatic.	• Discontinue ARVs. • Rechallenge with ENF is not recommended.

* The prescribing information for nevirapine states that patients experiencing rash during the 14-day lead-in period should not have the nevirapine dose increased until the rash has resolved. However, prolonging the lead-in phase beyond 14 days may increase the risk of nevirapine resistance due to subtherapeutic drug levels. Management of children who have persistent mild or moderate rash after the lead-in period should be individualized and consultation with an expert in HIV care should be obtained. Nevirapine should be stopped if the rash is severe or is worsening or progressing.

Key to Abbreviations: ABC = abacavir; ALT = alanine transaminase; APV = amprenavir; ARVs = antiretrovirals; AST = aspartate aminotransferase; ATV = atazanavir; ddI = didanosine; DRV = darunavir; EFV = efavirenz; EM = erythema multiforme; ENF = enfuvirtide; ETR = etravirine; FTC = emtricitabine; FPV = fosamprenavir; HSR = hypersensitiviy reaction; IDV = indinavir; IVIG = intravenous immune globulin; LPV/r = lopinavir/ritonavir; MVC = maraviroc; NNRTI = non-nucleoside reverse transcriptase inhibitor; NVP = nevirapine; PI = protease inhibitor; RAL = raltegravir; SJS = Stevens Johnson syndrome; TDF = tenofovir disoproxil fumarate; TEN = toxic epidermal necrolysis; TPV = tipranavir; ZDV = zidovudine

Table 17f. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Lipodystrophy, Lipohypertrophy, Lipoatrophy

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Lipodystrophy—General information		Onset: Trunk and limb fat initially increases within a few months of start of ART; however, peripheral fat wasting may not begin to appear for 12–24 months.	Adults: 2%–84% Children: 1%–33%, perhaps more common in adolescents than prepubertal children	• Genetic predisposition • Puberty • HIV-associated inflammation		
Central lipohypertrophy	• Most associated with PIs and EFV • Can occur in the absence of ART	Presentation: Central fat accumulation with increased abdominal girth, which may include dorsocervical fat pad (buffalo hump) and/or gynecomastia. The appearance of central lipohypertrophy is accentuated in the presence of peripheral fat wasting (lipoatrophy). In adults, waist circumference >102 cm (men) or >88 cm (women) is associated with increased risk of metabolic syndrome. For children and adolescents, waist circumference above the 75% percentile for age is associated with increased risk of metabolic syndrome.	See above	• PIs • EFV	Prevention: Diet and exercise. Monitoring: Measure waist circumference, waist to height ratio, and/or BMI (increase of each associated with development of metabolic syndrome).	• Diet and exercise, especially strength training. • Liposuction (Lipohypertrophy may reoccur after this cosmetic procedure; liposuction is not recommended for children.) • Recombinant human growth hormone or growth hormone-releasing hormone (investigational). • Metformin and rosiglitazone are not useful for treatment.

Facial/peripheral lipoatrophy	Most associated with thymidine analogue NRTI (d4T > ZDV)	Presentation: Thinning of subcutaneous fat in face, buttocks, and extremities, measured as decrease in trunk/limb fat by DXA or triceps skinfold thickness. Preservation of lean body mass distinguishes lipoatrophy from HIV-associated wasting.	Risk low in patients not treated with d4T or ZDV	• d4T and ZDV • Obesity prior to ART	Prevention: Avoid use of d4T and ZDV. Monitoring: Patient self-report and physical exam are the most sensitive methods of monitoring lipoatrophy.	• Switch from d4T or ZDV to other NRTIs if possible without loss of virologic control. • Poly-L-lactic acid is FDA approved for injection into areas of facial lipoatrophy in adults but difficult to use. Use is not reported for children. • Recombinant human leptin (investigational).

Key to Abbreviations: ART = antiretroviral therapy; ARVs = antiretrovirals; BMI = body mass index; d4T = stavudine; DXA = dual energy x-ray absorptiometry; EFV = efavirenz; FDA = Food and Drug Administration; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; ZDV = zidovudine

Table 17g. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Lactic Acidosis

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Lactic acidosis	NRTIs, in particular, d4T and ddI (each and in combination)	Onset: 1–20 months after starting therapy (median onset 4 months in one case series). Presentation: • Usually insidious onset of a combination of signs and symptoms: o Generalized fatigue, weakness, and myalgias o Vague abdominal pain, sudden weight loss, unexplained nausea or vomiting o Dyspnea o Peripheral neuropathy. • Patients may present with acute multi-organ failure (e.g., fulminant hepatic, pancreatic, and respiratory failure).	Chronic, asymptomatic mild hyperlactatemia (2.1–5.0 mmol/L): • *Adults*: 15%–35% of those receiving NRTI therapy longer than 6 months • *Children*: 29%–32% Symptomatic severe hyperlactatemia (>5.0 mmol/L): • *Adults*: 0.2%–2.5% Symptomatic lactic acidosis/hepatic steatosis: • Rare, but associated with a high fatality rate (33%–57%)	Adult risk factors: • Female gender • High BMI • Chronic HCV infection • African-American race • Prolonged NRTI use (particularly d4T and ddI) • Coadministration of ddI with other agents (e.g., d4T, TDF, ribavirin, or tetracycline) • CD4 count <350 cells/mm^3 • Acquired riboflavin or thiamine deficiency • Possibly pregnancy	Prevention: • Avoidance of d4T and ddI in combination. • Early recognition of clinical manifestations and adjustment of therapy. Monitoring: • *Asymptomatic*: Measurement of serum lactate is not recommended. • *Clinical signs or symptoms consistent with lactic acidosis*: Obtain blood lactate level*; additional diagnostic evaluations should include serum bicarbonate and anion gap and/or arterial blood gas, amylase and lipase, serum albumin, and hepatic transaminases.	Lactate 2.1–5.0 mmol/L (confirmed with second test): • Consider replacing ddI and d4T with other ARVs. • As alternative, temporarily discontinue all ARVs while conducting additional diagnostic work-up. Lactate >5.0 mmol/L (confirmed with second test)† or >10.0 mmol/L (any one test): • Discontinue all ARVs. • Provide supportive therapy (intravenous fluids; some patients may require sedation and respiratory support to reduce oxygen demand and ensure adequate oxygenation of tissues). • Anecdotal (unproven) supportive therapies: bicarbonate infusions, tris–hydroxymethyl-aminomethane (THAM), high-dose thiamine and riboflavin, oral antioxidants (e.g., L-carnitine, co-enzyme Q, vitamin C). • Following resolution of

Table 17g. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Lactic Acidosis

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
						clinical and laboratory abnormalities, therapy can be resumed, either with: o an NRTI-sparing regimen; or o a revised NRTI-containing regimen instituted with caution, using NRTIs less likely to inhibit mitochondria (ABC or TDF preferred; possibly FTC or 3TC); and o monthly monitoring of lactate for at least 3 months.

* Blood for lactate determination should be collected without prolonged tourniquet application or fist clenching into a prechilled, gray-top, fluoride-oxalate-containing tube and transported on ice to the laboratory to be processed within 4 hours of collection.

† Management may be initiated before the results of the confirmatory test.

Key to Abbreviations: 3TC = lamivudine; ABC = abacavir; ARVs = antiretrovirals; BMI = body mass index; d4T = stavudine; ddI = didanosine; FTC = emtricitabine; HCV = hepatitis C virus; NRTI = nucleoside reverse transcriptase inhibitor; TDF = tenofovir disoproxil fumarate

Table 17h. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations – Osteopenia, Osteoporosis, Osteonecrosis

Adverse Effects	Associated ARVs	Onset/Clinical Manifestations	Estimated Frequency	Risk Factors	Prevention/ Monitoring	Management
Osteopenia and osteoporosis	Following initiation of combination therapy, regardless of regimen. Specific agents of possible concern: TDF, d4T, or PIs.	Onset: Any age; greatest risk in months after initiation of associated ARV Presentation: Most commonly asymptomatic; fracture (rare) Note: Osteoporosis diagnosis in children requires clinical evidence of bone fragility and cannot rely solely on measured low bone density.	Low bone density: 20% of children treated with combination ARV therapy had BMD z score <-1.5	• Longer duration of HIV infection • Greater severity of HIV disease • Growth delay, pubertal delay • Low BMI • Lipodystrophy • Nonblack race • Smoking • Steroid use, medroxyprogesterone	Prevention: • Ensure calcium and vitamin D sufficiency. • Encourage weight-bearing exercise. • Minimize modifiable risk factors (smoking, low BMI, steroid use). Monitoring: • Assess nutritional intake (calcium, vitamin D, and total calories). • Serum 25-OH-Vitamin D.* • DXA.†	• Ensure calcium and vitamin D sufficiency. • Encourage weight-bearing exercise. • Reduce modifiable risk factors (smoking, low BMI, steroids, medroxyprogesterone). • Role of bisphosphonates not established in children. • Consider change in ARV regimen.
Osteonecrosis	No specific ARV identified. May be related to HIV infection itself.	Onset: Any age Presentation: • Limp; hip or other periarticular pain • Asymptomatic reported in adults	Prevalence: 0.2% in children Incidence: 0.03% per year in children	Children: Unknown Adults: • Steroid use • Alcohol abuse • Hemoglobinopathies • Hyperlipidemia • Pancreatitis • Osteopenia, osteoporosis • Hypercoagulable states	Prevention: Minimize steroid and alcohol use. Monitoring: Consider diagnostic evaluation in patients with unexplained limp, hip or other periarticular pain.	Confirm diagnosis: Plain radiographs and MRI; bone scan or CT if negative x-ray/MRI but clinical suspicion high. Treatment: • *Early stages*: decreased weight bearing on affected joint and use of analgesic. • *Later stages*: surgical intervention.

*Some experts would periodically measure 25-OH-Vitamin D, especially in HIV-infected urban youth because of high prevalence of vitamin D insufficiency.

† Until more data are available about the long-term effects of tenofovir on bone mineral acquisition in childhood, some experts would obtain a DXA at baseline and every 6 to 12 months for children in early puberty who are initiating treatment with tenofovir.

Key to Abbreviations: ARVs = antiretrovirals; BMI = body mass index; CT = computed tomography; d4T = stavudine; DXA = dual energy x-ray absorptiometry; MRI = magnetic resonance imaging; PIs = protease inhibitors; TDF = tenofovir disoproxil fumarate

Antiretroviral Treatment Failure in Infants, Children, and Adolescents (Updated August 16, 2010)

OVERVIEW

Panel's Recommendations:

- ***The goal of therapy following treatment failure is to achieve and maintain virologic suppression, as measured by a plasma viral load below the limits of detection using the most sensitive assay (AI*).***
- ***When complete virologic suppression cannot be achieved, the goals of therapy are to preserve or restore immunologic function (as measured by CD4 lymphocyte values), prevent clinical disease progression, and preserve future antiretroviral options (AII).***
- ***Not all instances of treatment failure require an immediate change in therapy; careful assessment, especially of adherence, is required to evaluate the etiology of the treatment failure and determine an appropriate management strategy (AII).***
- ***Children who experience treatment failure should be managed in collaboration with a pediatric HIV specialist (AI*).***

Although many children can remain on stable antiretroviral therapy for several years *[1-4]*, at some point reassessment of a therapeutic regimen will become necessary. This section will discuss the definitions, causes, assessment, and management of antiretroviral treatment failure and specific issues to consider when changing a drug regimen. Treatment failure is defined as suboptimal response or a lack of sustained response to therapy using virologic, immunologic, and clinical criteria. It is important to recognize that not all instances of treatment failure require an immediate change in antiretroviral therapy, and a careful assessment is required to evaluate the etiology of treatment failure and determine the appropriate management strategy.

Although the approach to treatment failure is generally straightforward after failure of the first regimen, it is typically more complex for children who have received more than one antiretroviral regimen. However, with the recent development of new antiretroviral agents, including those directed at new viral targets, the goal of treatment regimens for all patients—whether on initial, second, or subsequent regimen—is complete virologic suppression, combined with the recovery or maintenance of immunologic parameters and improvement in baseline clinical condition (or maintenance of clinical condition if asymptomatic). (See **Assessment of Patients with Antiretroviral Treatment Failure** and **Management of Medication Toxicity or Intolerance**). Decisions regarding changing antiretroviral therapy may need to be individualized and should take into consideration the child's treatment history and toxicities; prior and current detection of drug-resistant virus; current virologic, immunologic, and clinical status; ability to adhere to a new regimen; and available treatment options. In the context of these complexities it is recommended that all children being evaluated for treatment failure be managed in collaboration with a pediatric HIV specialist.

Developmental as well as behavioral characteristics distinguish adolescents from adults and affect decisions around management of treatment failure (see **Specific Issues in Antiretroviral Therapy for HIV-Infected Adolescents**). Drug metabolism may vary during puberty, necessitating a reassessment of medication dosing throughout adolescence. In some instances, young adults may require larger doses by weight or by surface area than older adults. In addition, dosing recommendations for adolescents have not been established for a number of new antiretroviral medications now used in adults. Dosing guidance for children and adolescents for all antiretroviral agents can be found in **Appendix B: Pediatric Antiretroviral Drug Information**. The ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*** can provide additional information to help inform management of antiretroviral treatment failure in adolescents.

Definition of Treatment Failure (see Table 12):

Treatment failure is categorized as virologic, immunologic, and clinical failure. Laboratory results must be confirmed with repeat testing before making a final assessment of virologic or immunologic treatment failure.

Virologic Failure: Virologic failure occurs as an incomplete response to therapy or a viral rebound after achieving virologic suppression.

- **Incomplete viral response to therapy:** Incomplete virologic response to therapy is defined for all children as a <1.0 $\log_{10}$ decrease in HIV RNA copy number from baseline after 8–12 weeks of therapy, HIV RNA >400 copies/mL after 6 months of therapy, or repeated HIV RNA greater than the level of detection using the most sensitive assay after 12 months of therapy. Children with higher HIV RNA levels at initiation of therapy, especially infants, may take longer to reach undetectable viral load.
- **Viral rebound:** For children who have previously achieved undetectable plasma viral load in response to therapy, viral rebound is defined as subsequent, repeated detection of plasma HIV RNA on ultrasensitive PCR assays. Infrequent episodes of low level viremia (<1,000 copies/mL) are common and not generally reflective of virologic failure, whereas repeated or persistent viremia (especially if >1,000 copies/mL) more likely represents viral rebound.

Immunologic Failure: Evaluation of immune response in children is complicated by the normal age-related changes in CD4 cell count discussed previously (see **Immunologic Monitoring in Children**). Thus, the normal decline in CD4 values with age needs to be taken into account when evaluating declines in CD4 parameters. CD4 percentage tends to vary less with age; absolute CD4 count values in children approach those of adults at about 5 years of age. Consequently, changes in absolute count may be used in children ≥5 years of age.

- **Incomplete immunologic response to therapy:** This is defined as a failure to improve CD4 values by ≥5 percentage points in a child <5 years of age with severe immune suppression (CD4 percentage <15%) or as a failure to improve CD4 values by ≥50 cells/mm^3 above baseline within the first year of therapy in a child age 5 years old or older with severe immune suppression (CD4 <200 cells/mm^3).
- **Immunologic decline:** This is defined as a sustained decline of 5 percentage points in CD4 percentage below pretherapy baseline at any age or decline to below pretherapy baseline in absolute CD4 cell count in children who are ≥5 years of age. Declines that represent a change to a more advanced category of immunosuppression compared with baseline (e.g., from CD4 percentage of 28% to 23% or from CD4 count of 250 cells/mm^3 to 150 cells/mm^3) or to more severe immunosuppression in those already suppressed at baseline (e.g., from CD4 percentage of 14% to 9% or from CD4 count of 150 cells/mm^3 to 100 cells/mm^3) are of particular concern.

Clinical Failure: The occurrence of new opportunistic infections and/or general clinical disease progression represents the most urgent and concerning type of treatment failure and should prompt an immediate evaluation. Clinical findings should be viewed in the context of virologic and immunologic response to therapy; in patients with stable virologic and immunologic parameters, development of clinical symptoms may not represent treatment failure. For example, development of a new opportunistic infection in a patient who had severe immune suppression at the time of recent initiation of therapy may not reflect failure of virologic suppression, but rather persistence of immune dysfunction despite adequate virologic response. Additionally, immune reconstitution inflammatory syndrome (IRIS) should be excluded as a possible cause of clinical symptoms before it is concluded that there is suboptimal clinical response to therapy. Although clinical events occurring in the first several months after antiretroviral initiation should not necessarily be construed as antiretroviral treatment failure, the occurrence of significant clinical disease progression, such as noted below, requires strong consideration that the current treatment regimen is failing:

- **Progressive neurodevelopmental deterioration:** The presence of two or more of the following findings documented on repeated assessments: impairment in brain growth, decline of cognitive function documented by psychometric testing, or clinical motor dysfunction.

- **Growth failure:** Persistent decline in weight-growth velocity despite adequate nutritional support and without other explanation.
- **Severe or recurrent infection or illness:** Recurrence or persistence of AIDS-defining conditions or other serious infections.

Children who experience treatment failure do not always require an immediate change in therapy; careful assessment is required to evaluate the etiology of the treatment failure and determine an appropriate management strategy (see **Assessment of Patients with Antiretroviral Treatment Failure**).

Discordance between Viral, Immune, and Clinical Responses

In general, effective combination antiretroviral therapy that results in virologic suppression also leads to immune restoration or preservation as well as to prevention of new or recurrent HIV-related illnesses. Similarly, ineffective antiretroviral therapy that fails to achieve virologic suppression is commonly accompanied by concordant immunologic and clinical failure *[5]*. However, clinicians may also be presented with patients in whom antiretroviral therapy is associated with failure in one domain (e.g., virologic failure) but a good response in the other domains (e.g., immunologic and clinical response). In fact, the discordance in responses to antiretroviral therapy may occur in any of these three domains in relation to the other two. It is essential to consider potential alternative causes of discordant responses before concluding that antiretroviral treatment failure has truly occurred.

Adequate Clinical and Immunologic Responses despite Incomplete Virologic Response: Some patients who are maintained on combination antiretroviral therapy may maintain immunologic and clinical benefit despite detectable viral replication for up to 3 years *[6-15]*. This observation is the rationale for continuing nonsuppressive antiretroviral therapy for immunologic and clinical benefit in selected patients for whom a completely suppressive regimen is not available or practicable. The risks and benefits as well as the indications for this approach are discussed in **Approach to the Management of Antiretroviral Treatment Failure** and **Choice of Next Antiretroviral Regimen for Treatment Failure with Evidence of Drug Resistance**. The proposed mechanisms for immunologic and clinical benefit without complete virologic suppression are the maintenance of a lower viral load or the selection for strains harboring drug-resistance mutations that impair viral replication or virulence. Another potential explanation is that some of these children may have host genetic and/or virologic characteristics that would have allowed them to be either “slow-progressors” or “long-term nonprogressors” without therapy.

Poor Immunologic Response despite Virologic Suppression Regardless of Clinical Response: Poor immunologic response despite virologic suppression can occur in the context of adequate or poor clinical response. The first considerations in cases of poor immunologic response despite virologic suppression are to exclude laboratory error in CD4 or viral load measurements and to ensure that CD4 values have been interpreted correctly in relation to the natural decline in CD4 count over the first 5–6 years of life. Another laboratory consideration is that some viral load assays may not amplify all HIV groups and subtypes (e.g., HIV-1 non-M groups or non-B subtypes, HIV-2), resulting in falsely low or negative viral load results (see **Diagnosis of HIV Infection in Infants** and **Laboratory Monitoring of Pediatric HIV Infection**). Once lab results are confirmed, evaluation for adverse drug effects, medical conditions, and other factors that can result in lower CD4 values is necessary.

Additionally, in patients with baseline severe immunosuppression, it is common to achieve virologic suppression weeks to months before achieving immunologic recovery, resulting in a transient early treatment period of persistent immunosuppression during which additional clinical disease progression can occur. Patients who have very low baseline CD4 values prior to initiating combination therapy are at higher risk of an impaired CD4 lymphocyte response to antiretroviral therapy and may be at higher risk of death and AIDS-defining illnesses, despite virologic suppression *[3, 12, 16-20]*.

Certain antiretroviral regimens may be associated with a blunted CD4 response. Treatment with a regimen containing tenofovir and didanosine can blunt the CD4 response, especially if the didanosine dose is not adjusted downward *[21]*. In adults, antiretroviral regimens containing zidovudine may also impair rise in CD4 count but not CD4 percentage, perhaps through the myelosuppressive effects of zidovudine; fortunately, this suboptimal CD4 count response to therapy does not seem to confer an increased risk of clinical events *[22]*.

Several drugs (e.g., corticosteroids, chemotherapeutic agents) and other conditions (e.g., hepatitis C, tuberculosis, malnutrition, Sjogren's syndrome, sarcoidosis) are independently associated with low CD4 values. Occasional cases of idiopathic CD4 lymphocytopenia have also been reported in adults without HIV infection *[23]*.

Differential Diagnosis of Poor Immunologic Response despite Virologic Suppression:

Poor Immunologic Response despite Virologic Suppression and Good Clinical Response

- Lab error
- Normal age-related CD4 lymphocyte decline
- Low pretreatment CD4 lymphocyte count or percentage
- Adverse effects of use of zidovudine or the combination of tenofovir + didanosine
- Use of systemic corticosteroids or chemotherapeutic agents
- Conditions that can cause low CD4 values: hepatitis C coinfection, Sjogren's syndrome, tuberculosis, sarcoidosis

Poor Immunologic and Clinical Responses despite Virologic Suppression

- Lab error, including HIV strain/type not detected by VL assay (HIV-1 non-M groups, non-B subtypes; HIV-2)
- Persistent immunodeficiency soon after initiation of antiretroviral therapy but prior to antiretroviral-related reconstitution
- Primary protein-calorie malnutrition
- Untreated tuberculosis
- Malignancy
- Loss of immunologic (CD4) reserve

Poor Clinical Response despite Adequate Virologic and Immunologic Responses: Clinicians must carefully evaluate patients who experience clinical disease progression despite favorable immunological and virological responses to antiretroviral therapy. Not all cases represent antiretroviral treatment failure. One of the most important reasons for new or recurrent opportunistic conditions despite achieving virologic suppression and immunologic restoration/preservation within the first months of antiretroviral treatment is immune reconstitution inflammatory syndrome (IRIS), which does not represent antiretroviral treatment failure and does not generally require discontinuation of antiretroviral treatment. Children who have suffered irreversible damage to their lungs, brain, or other organs, especially during prolonged and profound pretreatment immunosuppression, may continue to have recurrent infections or symptoms in those damaged organs because the damage may not be reversed by immunologic improvement *[24]*. Such cases do not represent antiretroviral treatment failure and would not be expected to benefit from a change in antiretroviral regimen. Evaluation for and treatment of other causes or conditions that can occur with or without HIV-related immunosuppression, such as pulmonary tuberculosis, malnutrition, and malignancy, should also be undertaken before drawing a conclusion of antiretroviral treatment failure. Occasionally, however, children will develop new HIV-related opportunistic conditions (e.g., *Pneumocystis jiroveci* pneumonia [PCP] or esophageal candidiasis occurring more than 6 months after achieving markedly improved CD4 values and virologic suppression) not explained by IRIS, pre-existing organ damage, or another reason. Such cases may be antiretroviral treatment failure and suggest that improvement in CD4 values may not necessarily represent return of complete immunologic function.

Differential Diagnosis of Poor Clinical Response despite Adequate Virologic and Immunologic Responses:

- IRIS
- Previously unrecognized pre-existing infection or condition (tuberculosis, malignancy)
- Malnutrition
- Clinical manifestations of previous organ damage: brain (strokes, vasculopathy), lungs (bronchiectasis)
- Clinical event due to non-HIV illness or condition
- New, otherwise unexplained HIV-related clinical event (treatment failure)

Table 18. Considerations for Changing Antiretroviral Therapy for Human Immunodeficiency Virus (HIV)-Infected Children

Virologic Considerations*	• **Incomplete viral response to therapy:** Incomplete virologic response to therapy is defined for all children as a <1.0 $\log_{10}$ decrease in HIV RNA copy number from baseline after 8–12 weeks of therapy, HIV RNA >400 copies/mL after 6 months of therapy, or repeated HIV RNA above the level of detection using the most sensitive assay after 12 months of therapy.† • **Viral rebound:** For children who have previously achieved undetectable plasma viral load in response to therapy, viral rebound is defined as subsequent, repeated detection of plasma HIV RNA on ultrasensitive PCR assays. Infrequent episodes of low level viremia (<1,000 copies/mL) are common and not generally reflective of virologic failure, whereas repeated or persistent viremia (especially if >1,000 copies/mL) more likely represents viral rebound.‡
Immunologic Considerations*	• **Incomplete immunologic response to therapy:** Failure in a child <5 years of age with severe immune suppression (CD4 percentage <15%) to improve CD4 values by ≥5 percentage points or failure in a child ≥5 years of age with severe immune suppression (CD4 <200 cells/mm^3) to improve CD4 values by ≥50 cells/mm^3 above baseline within the first year of therapy. • **Immunologic decline:** Sustained decline of 5 percentage points in CD4 percentage below pretherapy baseline at any age or decline to below pretherapy baseline in absolute CD4 cell count in children who are ≥5 years of age.§
Clinical Considerations	• **Progressive neurodevelopmental deterioration:** Two or more of the following on repeated assessments: impairment in brain growth, decline of cognitive function documented by psychometric testing, or clinical motor dysfunction. • **Growth failure:** Persistent decline in weight-growth velocity despite adequate nutritional support and without other explanation. • **Severe or recurrent infection or illness:** Recurrence or persistence of AIDS-defining conditions or other serious infections.

* At least two measurements (taken 1 week apart) should be performed before considering a change in therapy.

† The initial HIV RNA level of the child at the start of therapy and the level achieved with therapy should be considered when contemplating potential drug changes. For example, an immediate change in therapy may not be warranted if there is a sustained 1.5–2.0 $\log_{10}$ decrease in HIV RNA copy number, even if RNA remains detectable at low levels. Additionally, virologic suppression may take longer in young children given their higher viral load at the time of initiation of therapy than in older children or adults.

‡ Continued observation with more frequent evaluation of HIV RNA levels should be considered if the HIV RNA increase is limited (i.e., <5,000 copies/mL), especially in children with limited treatment options. The presence of repeatedly detectable or increasing RNA levels suggests the development of resistance mutations and/or nonadherence.

§ Declines that represent a change to a more advanced category of immunosuppression compared with baseline (e.g., from CD4 percentage of 28% to 23% or from CD4 count of 250 cells/mm^3 to 150 cells/mm^3) or to more severe immunosuppression in those already suppressed at baseline (e.g., from CD4 percentage of 14% to 9% or from CD4 count of 150 cells/mm^3 to 100 cells/mm^3) are of particular concern.

ASSESSMENT OF PATIENTS WITH ANTIRETROVIRAL TREATMENT FAILURE

Panel's Recommendations:

- ***Assess adherence to therapy and barriers and interventions to improve adherence because inadequate adherence is the most common cause of antiretroviral treatment failure (AII).***
- ***Assess medication intolerance (AIII).***
- ***Assess issues related to pharmacokinetics because developmental and individual differences in drug absorption, distribution, metabolism, and elimination can cause inadequate antiretroviral drug exposure that results in antiretroviral treatment failure (AII).***
- ***Perform antiretroviral drug-resistance testing when virologic failure occurs and prior to changing to a new regimen (AI*).***
- ***Perform assessment in collaboration with a pediatric HIV specialist (AI*).***

Each patient with an incomplete response to therapy should be assessed to determine the cause of treatment failure because the approach to management and subsequent treatment may differ depending on the etiology of the problem. In most instances, treatment failure is multifactorial. The assessment of a child with suspicion of treatment failure should include evaluation of adherence to therapy; medication intolerance; issues related to pharmacokinetics that could result in low drug levels or elevated, potentially toxic levels; and evaluation of suspected drug resistance. The main challenge to long-term maintenance of undetectable plasma viral load in adults and children is incomplete adherence to medication regimens, with the subsequent emergence of viral mutations conferring partial or complete resistance to one or more of the components of the antiretroviral regimen.

Table 13 outlines a comprehensive approach to evaluating causes of treatment failure in children, with particular attention to adherence. An extensive history should focus on the details of drug administration as well as changes in the social and psychological circumstances of the family likely to impact the child's ability to adhere to therapy. In some situations, it may be necessary to directly observe drug-taking behaviors either in the clinic, at home, or within the hospital because history alone may not fully identify the barriers to complete adherence *[1-2]*.

Adherence Issues (For more details, see **Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents** and **Table 11**.)

When treatment failure is observed, clinicians need to assess the likely contribution of adherence problems to the failure of the current regimen. In patients on initial therapy, poor virologic response or widely fluctuating viral loads are commonly an indication of poor adherence, particularly in the presence of susceptible virus. Even small lapses in adherence can lead to antiretroviral treatment failure *[3-7]*. Although adherence should be addressed at each medical visit for all children receiving antiretroviral therapy, suspicion of treatment failure warrants increased scrutiny. Patterns of adherence can change over time and may be influenced by a large number of factors related to the drugs themselves as well social and psychological issues of the child and the family.

Evaluation of whether adherence problems are related to drug formulation, number of pills, drug dose timing and frequency, food or fasting requirements, or drug side effects is important for determining what changes would be best suited to the individual requirements of the child and family. Intensive family education, training in the administration of prescribed medications, and discussion of the importance of adherence to the drug regimen should be reinforced. If competing family needs are identified as impediments to adherence, social issues may need to be addressed before adherence can be improved. Issues to be addressed may include achieving financial or housing security, assessing concomitant mental health problems, accessing substance abuse treatment, and

initiating a discussion around HIV disclosure. In some situations, clinicians may need to involve outside agencies such as child protective services to ensure support of the child's treatment. Various interventions should be considered if problems within the household are extreme and unlikely to resolve in favor of successfully supporting the child's treatment. Frequent patient visits and intensive follow-up may be necessary to support new adherence interventions and efforts by the child and family to improve adherence to the current or new regimen. Directly observed therapy (DOT) may be used to identify additional factors impeding adherence as well as to confirm drug administration.

Pharmacokinetic Issues

In addition to poor adherence, inadequate drug exposure can result in treatment failure *[8]*. Children consistently require higher weight-based dosing of antiretroviral drugs compared with adults because of developmental differences in absorption, body composition, and metabolic activity through the pediatric age range *[9]*. Causes of subtherapeutic drug levels may include failure to increase dosing for rapid growth of the child or impaired absorption because of gastrointestinal symptoms, such as vomiting or diarrhea. Drug exposure may be enhanced or reduced by administering medications with food; the clinician should review the food/fasting requirements of the regimen with the patient and caregiver. Drug interactions can alter drug metabolism; all concomitant medications, including over-the-counter medications and nutritional and herbal supplements, should be reviewed to evaluate whether they may be contributing to poor treatment response. (See the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.) Several recent studies suggest that genetic polymorphisms may influence pharmacokinetics and therapeutic response for a number of antiretroviral medications *[10-11]*. In some circumstances, therapeutic drug monitoring can be considered for children receiving selected drugs (see **Role of Therapeutic Drug Monitoring in Management of Treatment Failure**).

Suspected Drug-Resistance Issues (See **Antiretroviral Drug-Resistance Testing**.)

Antiretroviral drug resistance may develop in children with inadequate viral suppression. Genotypic resistance testing can help assess adherence to therapy. If testing reveals no resistance-associated mutations to the drugs of the current regimen, it is unlikely that the child is taking these medications. The presence of mutations supports inadequate drug exposure and failure to fully suppress viral replication. Antiretroviral resistance testing should be performed while the patient is still taking the failing regimen or within 4 weeks of its discontinuation. In the absence of the selective pressure of antiretroviral drugs, virus variants harboring resistance mutations may decrease in frequency to below the limits of detection of standard resistance assays. Resistance testing can be used to guide current management as well as to identify active antiretroviral medications for future regimens. Other laboratory tests such as tropism assays may be indicated as well if CCR5 inhibitors are being considered for treatment in the subsequent regimen.

Table 19. Assessment of Antiretroviral Treatment Failure

Assessment	Method	Intervention
Adherence	1. Interview child and caretaker • Take 24-hour or 7-day recall • Get description of: o *WHO* gives medication o *WHAT* is given (names, doses) o *WHERE* medications are kept, administered o *WHEN* they are taken/given • Have open-ended discussion of experiences taking/giving medications and barriers/challenges 2. Review pharmacy records • Assess timeliness of refills 3. Observe medication administration • Observe dosing/administration in clinic • Conduct home-based observation by visiting health professional • Admit to hospital for trial of therapy o Observe administration/tolerance o Monitor treatment response 4. Conduct psychosocial assessment • Make a comprehensive family-focused assessment of factors likely to impact adherence with particular attention to recent changes: o Status of caregiver, financial stability, housing, intimate relationships o School and achievement o Substance abuse (child, caretaker, family members) o Mental health and behavior o Child/youth and caretaker beliefs about antiretroviral therapy o Disclosure status (to child and others)	Identify or re-engage family members to support/supervise adherence. Establish fixed daily times and routines for medication administration. Avoid confusion with drug names by explaining that drug therapies have generic names and trade names, and many agents are coformulated under a third or fourth name. Explore opportunities for facility or home-based directly observed therapy. Simplify medication regimen if feasible. Substitute new agents if single ARV is poorly tolerated. Consider gastric tube placement to facilitate adherence. Consider directly observed therapy (DOT). Use tools to simplify administration (pill boxes, reminders including alarms, integrated medication packaging for AM or PM dosing, others). Suggest relaxation techniques. Address competing needs through appropriate social services. Address and treat concomitant mental illness and behavioral disorders. Initiate disclosure discussions with family/child. Consider need for child protection services and alternate care settings when necessary.
Pharmaco-kinetics and Dosing	1. Recalculate doses for individual medications using weight or body surface area. 2. Identify concomitant medications including prescription, over-the-counter, and recreational substances; assess for drug-drug interactions. 3. Consider drug levels for specific antiretroviral drugs (see **Role of Therapeutic Drug Monitoring in Management of Treatment Failure**).	Adjust drug doses. Discontinue or substitute competing medications. Reinforce applicable food restrictions.
Resistance Testing	1. Perform genotypic and phenotypic resistance assays (see **Antiretroviral Drug-Resistance Testing**). 2. Perform tropism assay, as appropriate.

APPROACH TO THE MANAGEMENT OF ANTIRETROVIRAL TREATMENT FAILURE

Panel Recommendations:

- ***The causes of treatment failure, which include drug resistance, poor absorption of medications, poor adherence, inadequate dosing, and drug-drug interactions, should be assessed and addressed (AII).***
- ***When deciding how to treat a child with treatment failure, the probability of achieving durable suppression based on the prior treatment history, drug resistance, drug potency, and likelihood of adherence should be considered as well as the future options available should durable suppression not be achieved; in addition, the future availability and timing of novel agents should be considered (AII).***
- ***Children who experience treatment failure should be managed in collaboration with a pediatric HIV specialist (AI*).***

General

Once the causes of failure have been identified and addressed, the child should be assessed to determine whether a change in the antiretroviral regimen is necessary. This will depend on the urgency and likelihood of achieving and sustaining an undetectable plasma viral load. The immediacy of implementing a more effective treatment regimen depends on the immunologic status of the child, with the greatest urgency for patients with clinical disease progression or clinical failure. The likelihood of achieving and maintaining undetectable plasma viral load depends on the extent of drug resistance, the number and quality of available agents that are active against the child's virus, and the likelihood of adherence to the new regimen.

Timing of Initiation of a New Regimen: Relative Importance of Virologic Suppression and Immunologic Improvement

Because immunologic improvement typically results from achieving undetectable plasma viral load *[1]*, the urgency of re-establishing virologic suppression depends on the clinical and immunologic status of a child. For example, for older children or adolescents with very low CD4 cell counts (e.g., <200 cells/mm^3), a change in therapy may be critical to prevent further immunologic decline or clinical disease progression and is strongly recommended. A patient with less immunosuppression may not be at significant risk of clinical disease progression in the near future, so an immediate change in therapy is less urgent. However, continued treatment of a child with persistently detectable viremia increases the risk of immunologic or clinical disease progression and leads to further accumulation of resistance mutations, possibly further limiting future treatment options *[2]*.

Likelihood of Viral Suppression below the Limit of Detection Using the Most Sensitive Assay

When deciding whether to change a child's antiretroviral regimen, a clinician must assess whether such a change is likely to achieve significantly better virologic control than the current regimen. Although complete virologic suppression should be the goal, this may not always be achievable in HIV-infected children. Clinical benefit may be observed with decrements in HIV RNA levels that do not result in undetectable levels *[1]*. However, failure to maximally suppress plasma viral load is associated with an increased probability of acquiring mutations associated with resistance. Anticipating and minimizing toxicities is central to the clinician-patient discussion. The likelihood of adherence to a new regimen plays a significant role in determining whether to change an antiretroviral regimen; if a child is unlikely to adhere to a new regimen, resistance will develop and sustainable virologic suppression will not be achieved. Although studies differ on the exact predictors of adherence, several contributing factors have been noted. These include medication characteristics *[3]*, psychosocial stressors *[4-5]*, health beliefs *[6]*, and prior adherence to medication (see **Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents** for more detail). Importantly, the pediatric patient's adherence to antiretroviral therapy may change over time as the child moves through progressive developmental stages, and any changes in these risk factors can occur rapidly and unexpectedly. Thus, a clinician may choose to target a new antiretroviral regimen to start at a time when the child is most likely to adhere to this regimen for a sustained period.

Categories of Children with Treatment Failure and Approaches to Consider

No Viral Resistance Identified

Persistent viremia in the absence of detectable viral resistance to current medications suggests that the virus is not being exposed to the antiretroviral agents. This lack of antiretroviral drug exposure is usually due to nonadherence, but it is important to exclude other factors such as poor drug absorption, incorrect dosing, and drug interactions. If adequate drug exposure can be assured, then resuming the existing current regimen should result in undetectable plasma levels. Resistance testing should take place while the child is on therapy, because predominant plasma viral strains may quickly revert to wild-type and fail to reveal the drug-resistant virus that would have been detectable while the patient was receiving therapy (see **Antiretroviral Drug-Resistance Testing**). Thus, if a child with prior therapy develops resistant virus and then stops therapy, sensitive virus will dominate in the absence of therapy. In this situation, resuming the prior therapy would fail to suppress the virus because the resistant virus would again emerge. An approach to identify resistance in this situation is to restart the prior medications while emphasizing adherence and repeating the resistance testing in 4 weeks (unless undetectable plasma viral load has already been achieved). If plasma virus is undetectable by ultrasensitive assays, it is likely that the virus is susceptible to the current therapy.

Viral Resistance to Current Therapy

The goal in this situation is to start a new regimen in order to fully suppress and sustain plasma viral load below the limits of detection and prevent the emergence of virus with additional resistance mutations. This requires a regimen that includes at least two, and preferably three, fully active agents. The choice of new agents should be based on current and past resistance testing (see **Antiretroviral Drug-Resistance Testing**), the antiretroviral history, availability of new drugs and classes of agents, and consideration of potential toxicities. Some antiretroviral drugs (e.g., NRTIs) may contribute partial antiretroviral activity to an antiretroviral regimen, despite drug resistance. Because of the potential for cross resistance of some drugs within a single class, substituting a new drug from the same previously used class does not assure that the replacement drug will be fully active. This is particularly true for the NNRTIs nevirapine and efavirenz, for which cross resistance with drug mutations is uniformly seen.

The availability of multiple new antiretroviral drugs, including some with new viral targets, makes complete virologic suppression achievable for many adult patients with treatment failure. Unfortunately, the lack of pediatric formulations and dosing information for many of these agents limits the number of options available for children. Thus, it remains difficult to identify a new, active regimen for many children with extensive prior therapy. (See **The Use of Antiretroviral Agents Not Approved for Use in Children**.)

If there is evidence of poor adherence to the current regimen and an assessment that good adherence to a new regimen would also be difficult, the emphasis and effort should be placed on addressing barriers to adherence. In such cases, some clinicians may choose to continue a nonsuppressive regimen that may provide some clinical and immunologic benefit while preserving future antiretroviral choices (see **Choice of Next Antiretroviral Regimen for Treatment Failure with Evidence of Drug Resistance**). Treating with the same nonsuppressive regimen in such situations should be regarded as an acceptable but not ideal short-term strategy. These patients should be followed more closely than patients with stable virologic status, and the potential to successfully initiate a fully suppressive antiretroviral regimen should be reassessed at every opportunity.

Extensive Drug Resistance Such That Two Fully Active Agents cannot be Identified or Administered

In the case of children for whom undetectable plasma virus is not achievable because two or more fully active agents cannot be identified, the goal is to preserve immunologic function and prevent clinical disease progression while preserving future options for new agents that are not yet available. Adult cohort studies suggest that there may be ongoing immunologic and clinical benefit if the HIV viral load can be maintained lower than 10,000–20,000 copies/mL *[7-8]*. Several cohort studies show a clinical benefit of remaining on antiretroviral therapy whether this leads to a decrease in the viral load. The principal risk associated with continuing a failing regimen is the development of additional resistance mutations that can limit future treatment options. Interrupting therapy completely, on the other hand, may cause a rapid increase in viral load, a decrease in CD4 cell count that is frequently persistent, and an increased risk of clinical disease progression *[4]*. This approach should only be considered in special circumstances when there is a low risk that therapy interruption will quickly lead to severe immunosuppression (i.e., CD4 values at the time of therapy interruption are high). The goal of continued treatment with an incompletely suppressive regimen is to select for resistant virus with reduced viral fitness that will cause slower disease progression while reducing the risk of drug toxicity and the development of new resistance mutations to multiple classes of drugs. The overall goal of these alternative strategies is to prevent clinical and immunological progression until additional active drugs are available that can be used to design a regimen that is expected to achieve undetectable plasma viral load *[1, 9-17]*. This approach should be regarded as acceptable but not ideal, these patients should be followed more closely than patients with stable virologic status, and the potential to successfully initiate a fully suppressive antiretroviral regimen should be reassessed at every opportunity.

When managing disease progression in a patient with advanced disease and extensive resistance, the patient's quality of life must be considered. The relative benefits (e.g., reduced viral fitness, continued clinical benefit

despite resistance, etc.) and burdens of continuing a failing antiretroviral regimen should be discussed. Decisions to continue, discontinue, or simplify antiretroviral therapy should be made collaboratively with patients, families, and clinicians and should be consistent with the patients'/families' stated values and goals for care.

CHOICE OF NEXT ANTIRETROVIRAL REGIMEN FOR TREATMENT FAILURE WITH EVIDENCE OF DRUG RESISTANCE

Panel's Recommendations:

- ***Antiretroviral regimens should be chosen based on treatment history and drug-resistance testing, including past and current resistance test results (AI*).***
- ***Ideally, use three fully active antiretroviral medications in the new regimen, assessing anticipated antiretroviral activity based on past treatment history and resistance test results (AII*).***
- ***Interpretation of resistance test results showing complex combinations of mutations and assessment of future treatment options should be made in collaboration with a pediatric HIV specialist (AI*).***
- ***Use of novel agents with limited available pharmacokinetic and/or safety data in pediatric populations should be undertaken only in collaboration with a pediatric HIV specialist (AIII).***

General

After carefully reaching a decision that a change in therapy is needed, the clinician should attempt to identify at least two but preferably three fully active antiretroviral agents on the basis of resistance testing, prior antiretroviral exposure, acceptability to the patient, and likely adherence *[1-5]*. This often requires the use of one or more new drug classes. Substitution or addition of a single drug to a failing regimen should be avoided because this approach is unlikely to achieve and sustain an undetectable plasma viral load and frequently will result in additional drug resistance. A drug may be "new" to the patient but have diminished antiviral potency due to the presence of drug mutations that confer cross resistance within a drug class. In children who are changing therapy due to occurrence or progression of abnormal neurodevelopment, the new treatment regimen should include agents (such as zidovudine) that are known to achieve higher levels within the central nervous system *[6-9]*.

A change to a new regimen must include an extensive discussion of treatment adherence and potential toxicity with the patient in an age- and development-appropriate manner and with the patient's caregivers. The clinician must recognize that conflicting requirements of some medications with respect to food and concomitant medication restrictions may complicate coordination of a regimen. Timing of medication administration is particularly important to ensure adequate antiretroviral drug exposures throughout the day. Palatability, pill size, pill number, and dosing frequency all need to be considered when choosing a new regimen.

Choice of Therapy with Viral Resistance to Current Therapy: Goal of Complete Virologic Suppression

Determination of a new regimen with the best chance for complete virologic suppression in children who have already experienced treatment failure should be made in collaboration with a pediatric HIV specialist. Antiretroviral regimens should be chosen based on treatment history and drug-resistance testing to optimize antiretroviral drug potency in the new regimen. A general strategy for regimen change is shown in **Table 14**, although as additional agents are licensed and studied for use in children, newer strategies that are better tailored to the needs of each patient may be constructed.

If a child has received initial therapy with an NNRTI-based regimen, a change to a PI-based regimen is recommended; if a child received initial therapy with a PI-based regimen, a change to an NNRTI-based regimen is recommended. Resistance to the NNRTI nevirapine results in cross resistance to the NNRTI efavirenz and vice versa; however, the newer NNRTI etravirine retains activity against nevirapine- or efavirenz-resistant virus in the presence of a limited number of NNRTI resistance-associated mutations. Etravirine is currently approved for use only in adults; pediatric studies are under way.

Choice of the new dual-NRTI component is particularly important when constructing a regimen because the choice of an insufficiently potent NRTI may result in the selection of additional NRTI-related drug mutations.

Resistance testing is essential to properly select a potent NRTI combination, and interpretation of these results should take place in collaboration with an expert in pediatric HIV infection (see **Antiretroviral Drug-Resistance Testing**). In this case, use of a triple-class regimen or a novel agent may be necessary.

If a patient has substantial pre-existing resistance or if the initial regimen contained drugs from all three major classes (NRTI, NNRTI, and PI), the drug-resistance profile and management approach is likely to resemble that of a patient who has had multiple antiretroviral regimen failures (see **Choice of Therapy with Extensive Drug Resistance Such That Two Fully Active Agents Cannot Be Identified or Administered**). In this situation, a new regimen with only two fully active agents may be the best available option. Lopinavir/ritonavir-based regimens have shown durable antiretroviral activity in antiretroviral treatment-experienced children, including children with prior PI therapy *[10-12]*. Adult studies of treatment-experienced patients have shown that using one or more new class(es) of drug (e.g., integrase inhibitors, entry inhibitors), possibly coupled with a ritonavir-boosted PI (e.g., darunavir) in PI-experienced, multiresistant patients is associated with better virologic responses *[13-14]*. **Appendix B: Pediatric Antiretroviral Drug Information** provides more detailed information on drug formulation, pediatric and adult dosing, and toxicity as well as discussion of available pediatric data for the approved antiretroviral drugs, including new drugs in existing classes such as darunavir and new classes of drugs such as CCR5 antagonists and integrase inhibitors. Maraviroc (CCR5 inhibitor) and raltegravir (integrase inhibitor) are approved for use in adolescents 16 years or older and can be considered for management of older adolescents with multidrug failure; pediatric trials are under way or in development.

Previously prescribed drugs discontinued due to poor tolerance or poor adherence may sometimes be reintroduced. Reintroduction of the drugs is particularly possible if antiretroviral resistance did not develop and if prior difficulties with tolerance and adherence can be overcome (e.g., by switching from a liquid to pill formulation). Limited data in adults suggest that continuation of lamivudine can contribute to suppression of HIV replication despite the presence of lamivudine resistance mutations and can maintain lamivudine mutations (184V) that can partially reverse the effect of other mutations conferring resistance to zidovudine, stavudine, and tenofovir *[15-17]*. The use of new drugs that have been evaluated in adults but have not been fully evaluated in children might be justified and is ideally done in the framework of a clinical trial (see **The Use of Antiretroviral Agents Not Approved for Use in Children**). Expanded access programs or clinical trials may be available. New drugs should be used in combination with at least one, and ideally two, additional active agents.

The HIV entry inhibitor enfuvirtide (T-20) has been approved for use in heavily treatment experienced patients based on potent antiretroviral activity in heavily treatment experienced adults and has been approved for use in children age ≥6 years *[18-19]*. Studies have helped establish safety, appropriate dosing, and efficacy of enfuvirtide in treatment-experienced children ≥6 years of age; this therapy has the disadvantage of administration by subcutaneous injection twice daily *[20-21]*. Enfuvirtide adherence in adolescent populations remains a unique challenge when compared with younger children. However, this agent should be considered as an option when designing a new regimen for pediatric populations who have failed treatment with multiple classes of antiretroviral medications.

Pharmacokinetic studies of certain dual-boosted PI regimens (lopinavir/ritonavir with saquinavir and lopinavir/ritonavir with atazanavir/ritonavir) suggest that pharmacokinetic targets for both PIs can be achieved or exceeded when used in combination in adults *[22-24]* and in children *[25-27]*. Pharmacokinetic studies of other dual-boosted PI combinations are limited but suggest inadequate drug levels of one or both PIs *[28-29]*. A study in Thailand of 50 PI-naïve but NRTI+/-NNRTI experienced children treated with a combination of lopinavir/ritonavir (230/57.5 mg/m^2 twice daily) and saquinavir (50 mg/kg twice daily, maximum dose 1,000 mg) demonstrated trough levels of both PIs at or above therapeutic targets and complete viral suppression at 48 weeks for ≥50% of patients. The regimen was well tolerated but hyperlipidemia was common. The use of multidrug regimens, sometimes including up to 3 PIs and/or 2 NNRTIs, has shown efficacy in a pediatric case series *[30]* but should be used cautiously due to its complexity, poor tolerability, and unfavorable drug-drug interactions. Therapeutic drug monitoring (TDM) may be helpful for confirming therapeutic PI levels when using PIs in combinations that result in complex drug interactions or when there is partially reduced PI activity

due to the presence of drug-resistance mutations (see **Role of Therapeutic Drug Monitoring in Management of Treatment Failure**).

When searching for at least two fully active agents in cases of extensive drug resistance, the clinician should consider the potential availability and future use of newer therapeutic agents that may not be studied or approved in children or may be in clinical development (see **The Use of Antiretroviral Agents Not Approved for Use in Children**). Information concerning potential clinical trials can be found at **http://aidsinfo.nih.gov/clinical_trials** and through collaboration with a pediatric HIV specialist. Children should be enrolled in clinical trials of new drugs whenever possible.

Choice of Therapy with Extensive Drug Resistance Such That Two Fully Active Agents Cannot Be Identified or Administered

The creation of an effective and sustainable therapeutic regimen may not be possible with currently available agents due to lack of potency in the face of extensive drug resistance or the patient's inability to adhere to or tolerate combination antiretroviral therapy. In such cases, nonsuppressive regimens (or "holding regimens") are sometimes used with the overall objective of preventing clinical and immunological deterioration pending availability of additional active drugs that can be used to design a regimen that is expected to achieve undetectable plasma viral load. This approach should be regarded as acceptable but not ideal. These patients should be followed more closely than patients with stable virologic status, and the potential to successfully initiate a fully suppressive antiretroviral regimen should be reassessed at every opportunity.

Even when NRTI drug-resistance mutations are present, there can be immunologic and clinical benefit despite persistent viremia when patients are treated with lamivudine monotherapy or when they are treated with lamivudine or emtricitabine in combination with one or more other NRTIs, such as zidovudine, stavudine, abacavir, or tenofovir *[31-32]*.

Because the newer NNRTI etravirine retains activity against nevirapine- or efavirenz-resistant virus in the presence of a limited number of NNRTI resistance-associated mutations, efavirenz or nevirapine should not be continued as part of a failing regimen if NNRTI resistance is documented.

Continued use of a PI in the face of persistent viremia can lead to accumulation of additional mutations conferring resistance to that PI as well as other, newer PIs. Such acquisition of additional PI drug resistance occurs slowly, especially if the viral load is relatively low *[33-35]*. However, continued PI use, in the presence of resistance, may limit viral replication and be beneficial to some patients.

In general, every effort should be made to avoid adding a single, new, fully active agent to these "holding" nonsuppressive regimens because such use of a single fully active agent will quickly lead to diminished activity of that agent. When clinical or immunologic deterioration occurs in such cases, it is often appropriate to use investigational agents or agents approved for older age groups as a second fully active drug in the new regimen (see **The Use of Antiretroviral Agents Not Approved for Use in Children**).

Table 20. Options for Regimens with at Least Two Fully Active Agents Following Failure of Antiretroviral Regimen with Evidence for Viral Resistance to Therapy with Goal of Virologic Suppression*

Prior Regimen	Recommended Change
2 NRTIs + NNRTI	• 2 NRTIs (based on resistance testing) + PI
2 NRTIs + PI	• 2 NRTIs (based on resistance testing) + NNRTI • 2 NRTIs (based on resistance testing) + alternative PI (with low-dose ritonavir boosting, based on resistance testing) • NRTI(s) (based on resistance testing) + NNRTI + alternative PI (with low-dose ritonavir boosting, based on resistance testing)
3 NRTIs	• 2 NRTIs (based on resistance testing) + (NNRTI *or* PI) • NRTI(s) (based on resistance testing) + (NNRTI + PI)
Failed regimens including NRTI, NNRTI, PI	• >1 NRTI (based on resistance testing) + a newer PI (with low-dose ritonavir boosting, based on resistance testing) • >1 NRTI + dual-boosted PI (LPV/r + SQV, LPV/r + ATV) (consider adding either one or more of T-20, ETR, or an integrase inhibitor) • NRTI(s) + ritonavir-boosted, potent PI (based upon resistance testing) + ETR • NRTI(s) + ritonavir-boosted, potent PI (based upon resistance testing) + T-20 and/or CCR5 antagonist and/or integrase inhibitor • If patient refuses PI and/or ritonavir boosting: NRTI(s) + T-20 and/or integrase inhibitor and/or CCR5 antagonist

* Antiretroviral regimens should be chosen based on treatment history and drug-resistance testing to optimize antiretroviral drug effectiveness in the second regimen. This is particularly important in selecting NRTI components of an NNRTI-based regimen where drug resistance may occur rapidly to the NNRTI if the virus is not sufficiently sensitive to the NRTIs. Regimens should contain at least two, but preferably three, fully active drugs for durable, potent virologic suppression.

Key to Abbreviations: T-20 = enfuvirtide, ATV = atazanavir, ETR = etravirine, LPV/r = lopinavir/ritonavir, NRTI = nucleoside reverse transcriptase inhibitor, NNRTI = non-nucleoside reverse transcriptase inhibitor, PI = protease inhibitor, SQV = saquinavir

THE USE OF ANTIRETROVIRAL AGENTS NOT APPROVED FOR USE IN CHILDREN

Panel's Recommendations:

- ***Some children with HIV need to use antiretrovirals that are not yet approved for their age range because many of the recently approved, more convenient, and potent agents are approved for adults before pharmacokinetic, safety, and efficacy data are available in children (AII).***
- ***This "off-label" use of antiretrovirals can be risky because dosing recommendations have not yet been made and often cannot be inferred from a simple calculation using the adult dose and the child's weight (AII).***
- ***Off-label use of antiretrovirals should always be done in collaboration with a pediatric HIV specialist, who may have access to unpublished data about safety and pharmacokinetics of these agents (AI*).***
- ***Whenever possible, use of antiretrovirals that are not yet FDA approved for children should be done in the context of clinical trials that can generate the data needed for pediatric approval (AIII).***

It has long been practice for physicians, especially pediatricians, to prescribe medications in "off-label" situations, meaning for indications or populations that do not fall within the FDA's official indication *[1]*. The relatively small market for pediatric antiretroviral drugs and few children available for clinical trials have delayed or prevented studies to obtain an FDA pediatric label indication for some antiretroviral drugs at the same time they are approved in adults. Pediatric HIV specialists may need to prescribe these agents because of

high levels of resistance seen in heavily treated children and adolescents and improvements in tolerability and ease of adherence with newer agents with less frequent dosing.

One distinct advantage of some of the newer medications is improved tolerability. Examples include a reduction in the number or severity of side effects with newer PIs and the ability to create simpler regimens using fixed-dose combination tablets or once-daily preparations. The incentive to use these drugs in such instances is that these regimens will lead to improved adherence and thus better long-term outcomes.

Another major factor leading to the off-label use of antiretrovirals has been the development of new drugs belonging to novel classes of agents effective against resistant virus. In the United States, many older perinatally infected children have extensive drug resistance resulting from incomplete viral suppression due to treatment with multiple nonsuppressive regimens. Cross resistance between fully approved antiretrovirals within a class complicates finding an array of agents likely to fully suppress the virus. In an effort to find a regimen likely to achieve complete virologic suppression in an individual patient, providers must find at least two and preferably three drugs with demonstrated activity against the patient's virus. Success is almost impossible in heavily treatment experienced children using only drugs with approved pediatric label indications; thus providers may use drugs not yet approved for children in order to provide optimal virologic response. The recent FDA approvals for adults of raltegravir and maraviroc (the first integrase inhibitor and CCR5 inhibitor, respectively) have provided new options for therapy to achieve virologic suppression in patients experiencing treatment failure with extensive antiretroviral resistance.

However, the use of agents not yet approved for pediatric use causes some difficulties, and one of the major issues is lack of data on appropriate dosing in children. Agents are approved for adult use prior to pediatric use because safety and pharmacokinetic studies in children have not yet been completed. Sometimes these studies are ongoing and some data are available, but other times these studies have not yet begun. It is essential for providers prescribing agents for off-label use to consult with pediatric HIV experts to avail themselves of the latest information from ongoing studies.

The possibility of age-related side effects is another concern when initiating off-label antiretroviral use. To date no antiretroviral has been found to have adverse effects that uniquely preclude use in children, but until an agent has been tested in children it cannot be considered to be free of such an effect. Additionally, adverse effects noted in adults may be of more substantial concern in the growing and developing child.

Even more difficult than the potential for adverse effects has been the difficulty of dosing of antiretrovirals in pediatric patients. As absorption, hepatic metabolism and excretion change with age, so will drug levels change in children *[2]*. The difficulty in dosing children as they increase in weight is exacerbated by changing pharmacokinetics. The direct extrapolation of the adult dose to a pediatric dose, based either on body weight or body surface area, has been shown in clinical trials of several antiretroviral agents to underestimate the appropriate pediatric dose *[3]*.

In summary, the use of antiretroviral agents without a pediatric indication is an absolute necessity for the treatment of some children with HIV, but it must be done with care. **It is essential that the provider consult with a pediatric HIV specialist to identify any particular concerns with each agent, to access any available data from clinical trials or other limited off-label pediatric use, and to investigate the availability of suitable clinical trials.**

ROLE OF THERAPEUTIC DRUG MONITORING IN MANAGEMENT OF TREATMENT FAILURE

Therapeutic drug monitoring (TDM) is the use of plasma drug concentration measurements as part of a strategy to optimize drug dosing to minimize toxicity and maximize treatment benefit. TDM can be considered for use in antiretroviral treatment because *[1]*:

- There is high interpatient variability in antiretroviral exposure (plasma drug concentrations) using standard recommended doses;
- Low drug exposure can lead to suboptimal virologic response to therapy; and
- High plasma concentrations can be associated with increased risk of drug toxicity.

Developmental pharmacokinetic differences contribute to greater variability and a greater frequency of suboptimal antiretroviral exposure in pediatric patients than in adults *[2]*. Pediatric dosing is designed to mimic adult exposure and rarely reflects the maximum tolerated antiretroviral drug dose. Even when using dose recommendations from published pediatric guidelines, children frequently receive inadequate antiretroviral doses *[3]*.

There are two main situations in which TDM might be useful in a child who is failing therapy. First, TDM can be used to rule out subtherapeutic drug levels as a cause of failure. Such inadequate drug levels could result from malabsorption, drug interactions, poor adherence, or increased drug metabolism or clearance. Second, drug levels can be used to optimize the dose of a drug when changing to a new regimen in a patient whose virus has a reduced susceptibility to that drug.

For TDM to be useful there needs to be a clearly defined relationship between antiretroviral concentrations and anti-HIV effects *[4-6]*. This association is strongest with PI and NNRTI drugs *[7]*, but maintaining adequate NRTI serum concentrations has also been shown to be important for maximal anti-HIV activity *[8]*. The exposure-toxicity response relationship is less well defined for NRTI drugs but has been determined for some agents *[6]*. Concentration-response relationships have been established with minimum plasma concentrations (C_{min} or C_{trough}) or area under the curve (AUC), but the optimal measure is not defined for all antiretroviral drugs *[9]*.

Table 15 presents recommendations for the minimum target trough concentrations of PIs and NNRTIs in patients with wild-type virus. In antiretroviral-experienced patients, the choice of minimum target trough concentration should be based on results of resistance testing *[10-12]*. Although it is intrinsically difficult to demonstrate benefit of TDM using double-blind studies, limited data suggest targeted concentrations can be achieved with TDM, clinical responses can be improved with increased or modified doses, and TDM information can be helpful in decision making *[7, 13-17]*. The clinician should consult with a pediatric HIV specialist or pharmacologist in making these decisions.

TDM is not recommended for routine use but may be considered in the following circumstances in which it is potentially useful:

- Patients in whom clinical response is different from that expected;

- Treatment-experienced patients infected with virus with reduced drug susceptibility, where a comparison of the drug susceptibility of the virus and the achieved drug concentrations may be useful;
- Patients with potential drug administration difficulties, including suboptimal dietary intake, malabsorption, incorrect dose, caregiver measuring errors, or adherence concerns; and
- Patients who experience drug or food interactions, including alteration of drug formulations by crushing or mixing with various foods and liquids.

Current limitations for pediatric antiretroviral TDM include:

- Prolonged time for laboratory processing in the face of potentially diminishing benefit the longer the patient is on inadequate therapy;
- Difficulties in coordinating sample collections at appropriate times make determination of true C_{min} or AUC difficult;
- High intrapatient variability from single drug concentration measurements may complicate interpretation of results *[18-19]*;
- Single trough measurements within the target range do not guarantee consistent adequacy of drug exposure or therapeutic success;
- Inadequate information on safety and effectiveness of dose adjustment strategies in children and adolescents;
- Limited availability of certified laboratories capable of assaying drug concentrations; and
- Lack of third party reimbursement of costs associated with TDM.

Table 21. Suggested Minimum Target Trough Concentrations*

Drug	Concentration (ng/mL)
Fosamprenavir	400 (measured as amprenavir concentration)
Atazanavir	150
Indinavir	100
Lopinavir	1,000
Nelfinavir (Measurable active [M8] metabolite)	800
Saquinavir	100–250
Efavirenz	1,000
Nevirapine	3,000
Recommendations applicable only to treatment-experienced persons who have resistant HIV-1 strains	
Maraviroc	>50
Tipranavir	20,500

DISCONTINUATION OR INTERRUPTION OF THERAPY

General

Discontinuation of antiretroviral therapy may be indicated in some situations, including serious treatment-related toxicity, acute illnesses or planned surgeries that preclude oral intake, lack of available medication, or patient or parent request. Although these events are usually unplanned, purposeful discontinuation of therapy has been widely used in the adult population to reduce toxicity, costs, and drug-related failure associated with antiretroviral therapy. At this time, there are minimal data in infants, children, and adolescents about planned structured treatment interruptions (STI). Thus, STI should not be attempted in children or adults outside of a clinical trial setting. The discussion below provides general guidance for the interruption of antiretroviral therapy and the risks and benefits in specific situations.

Short-Term Therapy Interruption

In the pediatric patient, short-term therapy interruptions are most often necessitated by acute illnesses that limit oral intake. These illnesses are often infectious diseases that result in vomiting and/or diarrhea. The clinician has no choice but to stop all therapy at the same time. Planned short-term interruption of therapy may also be required in the event of surgery or sedation for procedures, but when possible, the patient should be allowed to continue regular antiretroviral therapy with minimal fluid intake. If the period of restricted oral intake will be prolonged, then all therapy should be stopped at the same time if the medications have similar half-lives. In the case of serious or life-threatening antiretroviral therapy toxicity, all drugs should be stopped immediately.

When a short-term therapy interruption is indicated, all antiretroviral therapy should be stopped at the same time in most cases. This can be problematic with agents with a long half-life. Stopping agents with different half-lives at the same time can result in functional monotherapy with the drug with the longest half-life. This is particularly concerning in the case of the NNRTIs efavirenz and nevirapine.

Efavirenz and nevirapine have very long half-lives and can be detected for 21 days or longer after discontinuation *[1-4]*. As the other drugs with shorter half-lives are cleared, only nevirapine or efavirenz may persist, resulting in functional monotherapy, which can increase the risk of selection of NNRTI-resistant mutations. In addition, it is known that certain genetic polymorphisms may result in a slower rate of drug clearance. These polymorphisms may be more common among some ethnic groups, such as in African Americans and Hispanics *[3-4]*. To prevent this functional monotherapy, some experts recommend stopping the NNRTI first and continuing the other antiretroviral drugs (i.e., NRTI backbone or PI) for a period of time *[2]*. However, the optimal interval between stopping an NNRTI and the other antiretroviral drugs is not known. Detectable levels of NNRTIs may be present from less than 1 week to greater than 3 weeks after discontinuation *[4]*. An alternative is to substitute a PI for up to 4 weeks prior to the interruption of all drugs; however, there are no data to support this practice. Studies are ongoing in adults to help determine an effective

strategy. There is no information in children and, because the pharmacokinetics of these agents are different in children, the recommendations for adults may not be applicable *[5-7]*.

An additional consideration is reintroduction of nevirapine. Currently, a 2-week, half-dose escalation is recommended in patients who are started on nevirapine. Dose escalation is necessary because nevirapine induces its own metabolism by inducing CYP3A4 metabolic liver enzymes; thus, initial administration of the full therapeutic dose will result in elevated drug levels until metabolic enzyme induction has occurred. Lower rates of rash toxicity have been observed with the 2-week dose escalation *[5]*. In cases where nevirapine has been discontinued for more than 2 weeks, it is recommended that another 2-week dose escalation be used when the drug is reintroduced.

Long-Term Structured Treatment Interruptions

Long-term STIs have been proposed to reduce toxicities and costs associated with long-term antiretroviral therapy. STIs have also been proposed in patients who have limited treatment options to allow a return to their wild-type virus, which may be more susceptible to treatment. At this time, there is only minimal information about STI in children. In 1 study, children with controlled viral load (HIV RNA <400 copies/mL for $\geq$12 months) were subjected to increasing intervals of treatment interruption. Of 14 children studied, 4 maintained undetectable viral loads with interruptions of up to 27 days. It has been hypothesized that enhanced HIV-specific immune responses may play a role in the viral suppression *[8]*. However, new drug-resistance mutations were detected in 3 of 14 children in the STI study.

Recently, the results of two large, randomized clinical trials in adults have demonstrated inferior responses when CD4 cell count was used as an indication to stop and start therapy. The Strategies for Management of Antiretroviral Therapy stopped antiretroviral therapy when the CD4 cell count was >350 cells/mm^3 and reintroduced therapy when the count was <250 cells/mm^3. In comparison to the group receiving continuous antiretroviral therapy, the STI group had an increased risk of disease progression and death *[9]*. Similarly, in the Trivican trials, which used the same CD4 cell count triggers to stop and restart therapy, STI was shown to be inferior *[10]*. However, in studies in adults using a CD4 count <350 cells/mm^3 as a trigger to restart therapy, no significant difference in serious disease progression or death was seen *[11-12]*. A large cohort study in Italy showed an increased risk of disease progression after interruption of first-line therapy *[13]*. Several additional trials are currently ongoing in adults.

Many questions remain about STI in children and adolescents. In the United States and other developed countries, the majority of HIV-infected children began antiretroviral therapy during infancy *[14-15]*. Many of these children have had controlled viral replication for many years and are growing and developing normally. It is unclear if these children could discontinue therapy at some point and reinitiate based on CD4 cell decline. Although this has been speculated as plausible, there are no data to support this strategy and it should not be attempted outside of a clinical trial setting.

An additional scenario that is often raised is the patient who has limited treatment options and who, despite aggressive antiretroviral therapy, cannot reach an undetectable viral load. In these cases, interruption of therapy is generally not recommended because, despite detectable viral replication, immunologic benefit has been well documented *[16-19]*.

With either unplanned or STI therapy, the clinician should discuss the reasons and plans with the parent or guardian and, if applicable, the patient prior to proceeding. The parent and child should be made aware of the possibility of viral rebound resulting in a worsening of clinical symptoms, the risk of developing drug resistance, and the need for protection against opportunistic pathogens. The timelines and criteria for restarting therapy should be clear.

Antiretroviral Drug-Resistance Testing

(Updated August 16, 2010)

Panel's Recommendations:

- ***Antiretroviral drug-resistance testing is recommended prior to initiation of therapy in all treatment-naïve children (AII).***
- ***Antiretroviral drug-resistance testing is recommended prior to changing therapy for treatment failure (AI*).***
- ***Resistance testing in the setting of virological failure should be obtained while the patient is still on the failing regimen or within 4 weeks of discontinuing the regimen (AII*).***
- ***The absence of detectable resistance to a drug does not ensure that use of the drug will be successful, especially if the antiretroviral agent shares cross resistance with drugs previously used. In addition, current resistance assays are not sensitive enough to fully exclude the presence of resistant virus. Thus, previously used antiretroviral agents and previous resistance tests should be reviewed when making decisions regarding the choice of new agents for patients with virologic failure (AII).***
- ***Viral coreceptor (tropism) assays should be used whenever the use of a CCR5 antagonist is being considered (AI*). Tropism assays should also be considered for patients who demonstrate virologic failure while receiving therapy that contains a CCR5 antagonist (AI*).***
- ***Consultation with a specialist in pediatric HIV infection is recommended for interpretation of resistance assays when considering starting or changing an antiretroviral regimen in a pediatric patient (AI*).***

OVERVIEW OF HIV DRUG-RESISTANCE AND RESISTANCE ASSAYS

HIV replication is a continuous process in most untreated patients, leading to the daily production of billions of viral particles. The goal of antiretroviral therapy is to suppress HIV replication as rapidly and fully as possible, indicated by a reduction in plasma HIV RNA to below the limit of detection of the most sensitive assays available (<50–70 copies/mL). Unfortunately, mutations in HIV RNA readily arise during viral replication because HIV reverse transcriptase is a highly error-prone enzyme. Consequently, ongoing replication in the presence of antiretroviral drugs readily and progressively selects for strains of HIV with mutations that confer drug resistance.

Drug-resistance detection methods vary depending on the class of antiretroviral agents. Both genotypic assays and phenotypic assays are used to detect the presence of virus that is resistant to inhibitors of the HIV reverse transcriptase (RT), integrase, or protease (PR). Viral coreceptor (tropism) assays, a form of phenotypic assay, have been successfully employed in detecting the presence of virus with tropism that will (R5 tropism) or will not (X4 or mixed tropism) respond to CCR5 antagonists. Clinical experience with testing for viral resistance to other agents is more limited, but genetic mutations associated with resistance to integrase strand transfer inhibitors have been identified, and a commercial phenotypic assay is available for evaluation of resistance to the fusion inhibitor enfuvirtide (T20). Experience is also limited with the use of commercially available genotypic and phenotypic assays in the evaluation of drug resistance in patients infected with non-B subtypes of HIV *[1]*.

Genotypic Assays

Genotypic assays for resistance to RT, PR, and integrase strand transfer inhibitors are based on polymerase chain reaction (PCR) amplification and analysis of the RT, PR, and integrase coding sequences present in HIV RNA extracted from plasma. Genotypic assays can detect resistance-associated mutations in plasma samples containing approximately 1,000 copies/mL or more of HIV RNA, and results are generally available within 1–2 weeks of sample collection *[2]*. Interpretation of test results requires knowledge of the mutations selected by different antiretroviral drugs and of the potential for cross resistance to other drugs conferred by certain

mutations. For some drugs, there is a low genetic barrier to the development of resistance, and a single nucleotide mutation is enough to confer high-level resistance sufficient to remove any clinical utility. This is exemplified by resistance to nevirapine resulting from mutations in the HIV reverse transcriptase. Other mutations lead to drug resistance but simultaneously impair HIV replication. Clinically useful activity of the antiretroviral agent may therefore remain, as demonstrated by evidence of continued clinical benefit from lamivudine in individuals with evidence of the high-level resistance engendered by the M184V reverse transcriptase mutation *[3]*. Other mutations have little direct effect on resistance but arise during HIV evolution to high-level resistance or improve the replication of virus-bearing mutations that confer high-level resistance to an antiretroviral agent.

The International AIDS Society-USA (IAS-USA), the Los Alamos HIV Drug Resistance Database, and the Stanford University HIV Drug Resistance Database maintain lists of significant resistance-associated mutations relevant to currently available antiretroviral drugs (see **http://www.iasusa.org/resistance_mutations**, **http://hiv-web.lanl.gov** or **http://hivdb.stanford.edu**). A variety of online tools that take into account the ability of some mutations selected by one drug to cause partial or full cross resistance with other drugs are now available to assist the provider in interpreting genotypic test results. Although the response to antiretroviral therapy in children and adolescents is not always predicted by the results of genotypic resistance assays, clinical trials in adults have demonstrated the benefit of resistance testing combined with consultation with specialists in HIV drug resistance in improving virologic outcomes *[2, 4-10]*. Given the potential complexity of interpretation of genotypic resistance, it is recommended that clinicians consult with a specialist in pediatric HIV infection for assistance in the interpretation of genotypic results and design of an optimal new regimen.

Phenotypic Assays

Phenotypic resistance assays provide a more direct assessment of the impact of mutations acquired by mixture of virus strains present in an individual. As they are most often performed, phenotypic assays involve PCR amplification of the reverse transcriptase, integrase, protease, or other HIV gene sequences from patient plasma and insertion of those amplified patient sequences into the backbone of a laboratory strain of HIV. Replication of this recombinant virus at different drug concentrations is monitored by expression of a reporter gene and is compared with replication of a reference HIV strain. The drug concentration that inhibits viral replication by 50% (i.e., the median inhibitory concentration, or IC50) is calculated, and the ratio of the IC50 of test and reference viruses is reported as the fold increase in IC50 (i.e., fold resistance change). Automated, recombinant phenotypic assays are commercially available with results available in 2–3 weeks but are more costly than genotypic assays. In addition, interpretation of phenotypic assay results is sometimes complicated by the paucity of information about outcomes with specific levels of resistance.

Analytic techniques have also been developed to use the genotype to predict the likelihood of a drug-resistant phenotype. This bioinformatic approach, currently applicable for reverse transcriptase and protease inhibitor resistance only, matches the pattern of mutations obtained from the patient sample with a large database of samples for which both genotype and phenotype are known. Thus, the sample is assigned a predicted phenotype susceptibility (or "virtual phenotype") based on the data from specimens matching the patient's genotype. The primary limitation of this approach is that predictive power depends upon the number of matched phenotypic and genotypic assays, which may be limited for newer drugs.

Tropism (Viral Coreceptor Use) Assays

HIV enters cells by a complex multistep process that involves sequential interactions between the HIV envelope protein molecules and the CD4 receptor, then with either the CCR5 or CXCR4 coreceptor molecules, culminating in the fusion of the viral and cellular membranes. Viruses in the majority of untreated individuals, including infants and children infected by mother-to-child transmission of HIV, are initially CCR5 tropic. However, a shift in coreceptor tropism often occurs over time, from CCR5 usage to either CXCR4 or both CCR5 and CXCR4 tropism (dual- or mixed-tropic; D/M-tropic). Antiretroviral-treated patients with extensive drug resistance are more likely to harbor detectable X4- or D/M-tropic virus than untreated patients with comparable CD4 T-cell counts *[11]*.

Resistance to CCR5 antagonists is currently detected using the specialized phenotypic assay methods Phenoscript (VIRalliance, Paris, France) and Trofile (Monogram Biosciences, Inc). These assays involve the generation of recombinant viruses bearing patient-derived envelope proteins (gp120 and gp41). The relative capacity of these pseudoviruses to infect cells bearing the cell surface proteins CCR5 or CXCR4 is quantified based on the expression of a reporter gene. The Trofile assay takes about 2 weeks to perform and requires a plasma viral load ≥1,000 copies/mL. The initial version of the Trofile assay used during the clinical trials that led to the licensure of maraviroc was able to detect X4-tropic virus with 100% sensitivity when present at a frequency of 10% of the plasma virus population but only 83% sensitivity when the variant was present at a frequency of 5%. In initial clinical trials of CCR5 antagonist drugs, this sensitivity threshold was not always sufficient to exclude the presence of clinically meaningful levels of X4- or D/M-tropic virus in patients initiating a CCR5 inhibitor-based regimen. A newer version of the Trofile assay with improved sensitivity able to detect X4- or D/M-tropic virus representing as little as 0.3% of the plasma virus is now available *[12-13]*. Genotypic assays that may also prove useful in detection of X4 or D/M tropism are also under development. The detection of any usage of CXCR4 is a contraindication to the use of the CCR5 antagonists as part of a therapeutic regimen. Coreceptor use assays should be performed prior to the use of a CCR5 inhibitor and may be considered in patients exhibiting virologic failure on a CCR5 inhibitor such as maraviroc.

Use of Resistance Assays in Determining Initial Treatment

Mother-to-child transmission and horizontal transmission of drug-resistant HIV strains have been well documented and are associated with suboptimal virologic response to initial antiretroviral therapy *[14-18]*. Drug-resistant variants of HIV may persist for months after birth in infected infants *[19]* and impair the response to antiretroviral therapy *[20]*. Consequently, antiretroviral drug-resistance testing is recommended prior to initiation of therapy in all treatment-naïve children.

Use of Resistance Assays in the Event of Virologic Failure

Several studies *[2, 4-10]* have been performed in adults indicating that early virologic responses to salvage regimens were improved when results of resistance testing were available to guide changes in therapy, compared with responses observed when changes in therapy were guided only by clinical judgment. Although not yet confirmed in children *[21]*, resistance testing appears to be a useful tool in selecting active drugs when changing antiretroviral regimens in cases of virologic failure. Resistance testing also can help guide treatment decisions for patients with suboptimal viral load reduction because virologic failure in the setting of combination antiretroviral therapy may be associated with resistance to only one component of the regimen *[1]*. Poor adherence should be suspected when no evidence of resistance to a failing regimen is identified.

Limitations of Current Resistance and Tropism Assays

Limitations of the genotypic, phenotypic, and phenotype-prediction assay approaches include lack of uniform quality assurance testing and high cost. In addition, drug-resistant viruses that constitute <10%–20% of the circulating virus population may not be detected by any of the currently available assays. Consequently, a review of the past use of antiretroviral agents is important in making decisions regarding the choice of new agents for patients with virologic failure.

Although drug resistance may be detected in infants, children, and adults who are not receiving therapy at the time of the assay, loss of detectable resistance and reversion to predominantly wild-type virus often occur in the first 4–6 weeks after antiretroviral drugs are stopped *[22-24]*. As a result, resistance testing is of greatest value when performed before or within 4 weeks after drugs are discontinued. The absence of detectable resistance to a drug at the time of testing does not ensure that future use of the drug will be successful *[25]*, especially if the agent shares cross resistance with drugs previously used. It may be prudent to repeat resistance testing if an incomplete virological response to a new treatment regimen is observed in an individual with prior treatment failure(s) (see **Antiretroviral Treatment Failure in Infants, Children, and Adolescents**).

Conclusion

The care of HIV-infected children is complex and evolving rapidly as results of new research are reported and new antiretroviral drugs and newer classes of drugs are approved. Clinical trials to define appropriate drug dosing and toxicity in children ranging in age from infancy to adolescence are critical as new drugs become available. As additional antiretroviral drugs become approved and optimal use of these drugs in children becomes better understood, the Panel will modify these guidelines. It should be noted that guidelines are only a starting point for medical decision making and are not meant to supersede the judgment of clinicians experienced in the care of HIV-infected children. Because of the complexity of caring for HIV-infected children, health care providers with limited experience in the care of these patients should consult with a pediatric HIV specialist.

The Centers for Disease Control and Prevention, the National Institutes of Health, the HIV Medicine Association of the Infectious Disease Society of America, the Pediatric Infectious Disease Society, and the American Academy of Pediatrics jointly developed and published guidelines for the prevention and treatment of opportunistic infections in HIV-exposed and -infected children; these guidelines are available at **http://aidsinfo.nih.gov** *[1]*. Similar guidelines for adults are also available at the same Web site *[2]*.

Appendix B: Pediatric Antiretroviral Drug Information

NUCLEOSIDE AND NUCLEOTIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS

Abacavir (ABC, Ziagen)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Pediatric oral solution: 20 mg/mL
Tablets: 300 mg (scored)
Combination tablets:
- *with lamivudine (3TC)*: 600 mg ABC + 300 mg 3TC (Epzicom)
- *with zidovudine (ZDV) and lamivudine (3TC)*: 300 mg ABC + 300 mg ZDV + 150 mg 3TC (Trizivir)

Dosing Recommendations

Neonate/Infant dose:
Not approved for infants <3 months of age.

Pediatric dose:
Oral solution (≥3 months):
8 mg/kg (maximum 300 mg) twice daily

Scored 150 mg tablet (≥14 kg):

Weight (kg)	Twice-Daily Dosage Regimen		
	AM Dose	PM Dose	Total Daily Dose
14–21 kg	½ tablet (150 mg)	½ tablet (150 mg)	300 mg
>21–<30 kg	½ tablet (150 mg)	1 tablet (300 mg)	450 mg
≥30 kg	1 tablet (300 mg)	1 tablet (300 mg)	600 mg

Adolescent (≥16 years)/Adult dose:
300 mg twice daily or 600 mg once daily

Dosing Recommendations for Combination Formulations

Trizivir
Adolescent (≥40 kg)/Adult dose:
One tablet twice daily

Epzicom
Adolescent (>16 years)/Adult:
One tablet once daily

Selected Adverse Events

- Hypersensitivity reaction that may be fatal; symptoms may include fever, rash, nausea, vomiting, malaise or fatigue, loss of appetite, respiratory symptoms such as sore throat, cough, shortness of breath.
- Several observational cohort studies suggest increased risk of myocardial infarction in adults with recent or current use of ABC; however, other studies have not substantiated this finding, and there are no data in children.

Special Instructions

- Can be given without regard to food.
- Caution patients and parents about the risk of serious hypersensitivity reaction that can be fatal. Do not rechallenge.
- Test patients for the HLA-B*5701 allele prior to starting therapy to predict risk of hypersensitivity; patients with the HLA-B*5701 allele should not be given ABC. Patients with no prior HLA-B+5701 testing who are tolerating ABC do not need to be tested.

Metabolism

- Metabolized by alcohol dehydrogenase and glucuronyl transferase; renal excretion of metabolites 82%.
- ABC requires dosage adjustment in hepatic insufficiency. Do not use Trizivir and Epzicom (fixed-dose combination products) in patients with CrCl <50 mL/min, patients on dialysis, or patients with impaired hepatic function.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.):
- Abacavir does not inhibit, nor is it metabolized by, hepatic cytochrome P450 enzymes. Thus, it should not cause changes in clearance of agents metabolized through these pathways, such as PIs and NNRTIs.
- Abacavir is metabolized by alcohol dehydrogenase and glucuronyltransferase. Alcohol increases abacavir levels by 41%.

Major Toxicities:
- *More common:* Nausea, vomiting, fever, headache, diarrhea, rash, and anorexia.
- *Less common (more severe):* Serious and sometimes fatal hypersensitivity reactions observed in approximately 5% of adults and children (rate varies by race/ethnicity) receiving abacavir. Hypersensitivity to abacavir is a multi-organ clinical syndrome usually characterized by rash or by signs or symptoms in two or more of the following groups: (1) fever; (2)

constitutional, including malaise, fatigue, or achiness; (3) gastrointestinal, including nausea, vomiting, diarrhea, or abdominal pain; or (4) respiratory, including dyspnea, cough, or pharnygitis. Laboratory and imaging abnormalities include elevated liver function tests, elevated creatine phosphokinase, elevated creatinine, lymphopenia, and pulmonary infiltrates. This reaction generally occurs in the first 6 weeks of therapy and has occurred after a single dose. If a hypersensitivity reaction is suspected, abacavir should be stopped and **not restarted because hypotension and death have occurred upon rechallenge**. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Pancreatitis may occur.

- *Rare:* Increased liver enzymes, elevated blood glucose, elevated triglycerides, and possible increased risk of myocardial infarction (in observational studies in adults).

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/ABC.html**).

Pediatric Experience: Abacavir has been studied in HIV-infected children both separately and in combination with other antiretroviral drugs *[1-11]*. In the PENTA-5 trial, 130 HIV-infected antiretroviral-naïve children were randomly assigned to 1 of 3 different nucleoside analogue regimens: zidovudine/lamivudine, abacavir/zidovudine, and abacavir/lamivudine, with and without nelfinavir *[10]*. The 2 abacavir-containing regimens were associated with greater mean viral load decreases after 48 weeks of therapy than the zidovudine/lamivudine regimen (-1.71, -2.17, and -2.63 log copies/mL with zidovudine/lamivudine, abacavir/zidovudine, and abacavir/lamivudine, respectively). In this study, 4 children (3%) stopped abacavir due to a possible hypersensitivity reaction. After 5 years of follow-up in the PENTA-5 study, children who were treated with abacavir/lamivudine were significantly more likely to have HIV RNA levels <50 copies/mL than children treated with zidovudine/lamivudine or abacavir/ zidovudine (63% vs. 25 % or 32%, p = 0.003) and had significantly better improvement in height for age and weight for age *[5]*.

Pharmacokinetic studies of abacavir in children <12 years of age have demonstrated that children have more rapid clearance than adults and that pediatric doses approximately twice the directly scaled adult dose are necessary to achieve similar systemic exposure *[4, 6]*. Adolescents and young adults (ages 13 to 25) have clearance that is slower than younger children but still more rapid than that found in adults *[12]*. The PENTA-13 trial studied once-daily versus twice-daily dosing of abacavir in combination with lamivudine in 24 children age 2–13 years, with undetectable or low, stable virus load at the time of starting once-daily therapy, showing equivalent $AUC_{0\text{-}24}$ for both drugs and improved acceptability in the once-daily dosing arm *[1, 8]*. However, trough concentrations were lower for both abacavir and lamivudine in younger children (ages 2–6 years) receiving the once-daily regimen *[1]*. More long-term clinical trials with viral efficacy endpoints are needed to confirm that once-daily dosing of abacavir and lamivudine can be effectively used in children.

In pediatric populations, triple-NRTI-only combinations should be used only in special circumstances. In 1 study of 205 treatment-experienced children ranging in age from 0.7 to 13 years, only 10% of 102 children receiving abacavir/ zidovudine/lamivudine had HIV RNA concentrations <400 copies/mL after 48 weeks of therapy *[11]*. Several studies of abacavir as part of a PI-sparing 3-drug NRTI regimen (zidovudine, lamivudine, and abacavir) have been done in adults and show decreased antiretroviral potency of the triple-NRTI-only regimens *[13-17]*.

Didanosine (ddI, Videx)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/**

Formulations

Videx pediatric powder for oral solution: reconstituted 10 mg/ml
Videx EC delayed-release capsules (enteric-coated beadlets): 125 mg, 200 mg, 250 mg, and 400 mg
Generic ddI delayed-release capsules: 200 mg, 250 mg, and 400 mg

Dosing Recommendations

Neonate/Infant dose (2 weeks to <3 months):
50 mg/m^2 of body surface area every 12 hours
(Manufacturer recommends 100 mg/m^2 of body surface area every 12 hours in this age range. Panel members interpret PK data as suggesting potential increased toxicity at that dose in this age group and many would use 50 mg/m^2 of body surface area every 12 hours.)

Infant dose (>3 months to 8 months):
100 mg/m^2 of body surface area every 12 hours

Pediatric usual dose of oral solution (>8 months):
120 mg/m^2 of body surface area every 12 hours
(Dose range: 90–150 mg/m^2 of body surface area every 12 hours)

Pediatric dose of Videx EC or generic capsules (6–18 years and ≥20 kg):

Body Weight (kg)	Dose
20 kg to <25 kg	200 mg once daily
25 kg to <60 kg	250 mg once daily
≥60 kg	400 mg once daily

In treatment-naïve children 3–21 years of age, 240 mg/m^2 of body surface area once daily (oral solution or capsules) has been used with good viral suppression.

Adolescent/Adult dose:
<60 kg: 250 mg once daily
≥60 kg: 400 mg once daily

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs

ddI in combination with tenofovir (TDF)

Pediatric/Adolescent dose:
No data on combination in children or adolescents <18 years of age.

Adult dose:
<60 kg (limited data in adults): 200 mg once daily
≥60 kg: 250 mg once daily

Selected Adverse Events

- Peripheral neuropathy (dose related)
- Electrolyte abnormalities and hyperuricemia
- Diarrhea, abdominal pain, nausea, and vomiting
- Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases have been reported (increased risk when used in combination with stavudine [d4T])
- Pancreatitis (dose related, less common in children than adults, more common in adults when used in combination with TDF or d4T)
- Potential association with noncirrhotic portal hypertension

Special Instructions

- Food decreases absorption of all ddI preparations; administer ddI on an empty stomach (30 minutes before or 2 hours after a meal).
- ddI oral solution contains antacids that may interfere with the absorption of other medications.
- Shake oral solution well. Keep refrigerated; admixture is stable for 30 days.
- When coadministered, ddI delayed-release capsule formulation and TDF may be taken under fasted conditions or with a light meal.

Metabolism

- Renal excretion 50%.
- Dosing of ddI in patients with renal insufficiency: Decreased dosage should be used in patients with impaired renal function. Consult manufacturer's prescribing information for adjustment of dosage in accordance with creatinine clearance.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)*:*

- *Absorption:* The presence of antacids in the didanosine suspension has the potential to decrease the absorption of a number of medications if given at the same time. Many of these interactions can be avoided by the appropriate timing of doses.
- *Mechanism unknown:* Didanosine serum concentrations are increased when coadministered with tenofovir.
- *Renal elimination:* Drugs that decrease renal function could decrease clearance.
- *Enhanced toxicity:* Didanosine mitochondrial toxicity is enhanced by ribavirin.
- *Overlapping toxicities:* There is increased risk of pancreatitis and peripheral neuropathy with some NRTIs (e.g., stavudine). Combination of stavudine and didanosine is not recommended (unless the benefits clearly outweigh the risks) because of overlapping toxicities and reports of serious, even fatal, cases of lactic acidosis with hepatic steatosis with or without pancreatitis in pregnant women.

Major Toxicities:

- *More common:* Diarrhea, abdominal pain, nausea, and vomiting.
- *Less common (more severe):* Peripheral neuropathy (dose related), electrolyte abnormalities, and hyperuricemia. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Pancreatitis (dose related, less common in children than adults, more common in adults when used in combination with tenofovir), increased liver enzymes, and retinal depigmentation have been reported. The combination of stavudine with didanosine may result in enhanced toxicity (increased risk of fatal and nonfatal cases of lactic acidosis or pancreatitis); this combination should not be used unless the potential benefit clearly outweighs the potential risk.
- *Rare:* Noncirrhotic portal hypertension, with increased transaminases, increased alkaline phosphatase, and thrombocytopenia, has been associated with long-term didanosine use in adults [1].

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/ddI.html**).

Pediatric Experience: Didanosine has been studied in HIV-infected children as monotherapy and in combination with other antiretroviral drugs *[2-24]*. Recommended didanosine doses in children have traditionally been 90–150 mg per meter^2 body surface area per dose twice daily. Doses higher than 180 mg per meter^2 body surface area twice daily are associated with increased toxicity *[3]*. In a simulation based on didanosine concentration data from 16 children, a dose of 90 mg per meter^2 body surface area twice daily was predicted to result in adequate drug exposure in only 57% of pediatric patients, compared with a predicted 88% of patients at a dose of 120 mg per meter^2 body surface area *[6]*. This dose of 120 mg per meter^2 body surface area per dose twice daily has therefore become the "standard" dose of didanosine for older infants and children. Data from multiple pediatric studies of didanosine alone or in combination with other drugs, including a study of long-term didanosine use (median duration of almost 2 years), show that didanosine appears safe and is associated with clinical improvement, increase in CD4 count, and decrease in viral load *[5, 7-8, 11, 13, 15, 19]*.

Three major areas of controversy remain in the use of didanosine in the treatment of children with HIV infection: (1) the appropriate dose to use in infants 2 weeks to 4 months of age, (2) the need to dose didanosine on an empty stomach, and (3) the potential use of enteric-coated didanosine (Videx EC) once daily in children.

The "usual pediatric dose" of 120 mg per meter^2 body surface area per dose twice daily was used successfully in combination therapy in infants 2 to 16 months of age without significant toxicity *[18]*. Currently, the FDA recommends 100 mg per meter^2 body surface area per dose twice daily for infants from 2 weeks to 8 months of age, increasing to 120 mg per meter^2 body surface area per dose twice daily at age 8 months. However, two small studies suggest that higher AUCs are seen in infants <6 weeks of age and that a dose of 100 mg per meter^2 body surface area per day (either as 50 mg per meter^2 body surface area per dose twice daily or 100 mg per meter^2 body surface area once daily) achieves AUCs consistent with those of higher doses in older children *[9, 12]*. Therefore, because of pharmacokinetic differences in younger infants (2 weeks to 4 months) compared with older children, a dose of 50 mg per meter^2 of body surface area twice daily may be more appropriate in younger infants.

Although the prescribing information recommends taking didanosine on an empty stomach, this is impractical for infants who must be fed frequently and may decrease medication compliance by increasing regimen complexity. A comparison of didanosine given with or without food in children found that systemic exposure was similar, but with slower and more prolonged absorption *[20]*. To improve compliance, some practitioners recommend administration without regard to timing of

meals for young children. However, there are inadequate data to allow a strong recommendation at this time, and it is preferred that didanosine be administered under fasting conditions when possible.

Enteric-coated didanosine (Videx EC) administered as a single dose of 240 mg per meter^2 body surface area once daily has been shown to have similar plasma AUC (although lower peak plasma concentrations) compared with the equivalent dose of buffered didanosine *[9]*. The resultant intracellular (active) drug concentrations are unknown. In 24 children with HIV infection, didanosine at a dose of 180 mg per meter^2 body surface area once daily was compared with 90 mg per meter^2 body surface area twice daily, and the AUC was actually higher in the once-daily group than in the twice-daily group *[2]*. In fact, in 53 children with advanced symptomatic HIV infection, once- versus twice-daily didanosine at a dose of 270 mg per meter^2 body surface area per day showed no difference in surrogate marker or clinical endpoints, except that weight gain was poorer in the children given once-daily therapy *[14]*. A European trial of once-daily combination therapy in 36 children 3–11 years of age that included didanosine at a dose of 200–240 mg per meter^2 demonstrated safety and efficacy with 96 weeks of follow-up data *[25]*. Enteric-coated didanosine is currently approved for use in children ages 6 to 18 years who are able to swallow capsules whole and have a body weight of at least 20 kg.

In a study in the United States, long-term virologic suppression with a once daily regimen of efavirenz, emtricitabine, and didanosine (enteric-coated beadlet capsules) was reported in 37 treatment-naïve children, 3–21 years of age, participating in PACTG 1021 *[26]*. The didanosine dose used in that study was 240 mg/ meter^2/dose once daily, and pharmacokinetic analysis showed no dose changes were needed to reach PK targets *[26]*. Eighty-five percent of subjects were able to achieve HIV RNA <400 copies/mL and 72% maintained HIV RNA suppression to <50 copies/mL through 96 weeks of therapy.

Emtricitabine (FTC, Emtriva)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Pediatric oral solution: 10 mg/mL
Capsules: 200 mg
Combination tablets
- *With tenofovir (TDF):* 200 mg FTC + 300 mg TDF (*Truvada*)
- *With TDF and efavirenz (EFV):* 200 mg FTC + 300 mg TDF + 600 mg EFV (*Atripla*)

Dosing Recommendations

Neonate/Infant Dose (0–3 months):
Oral solution: 3 mg/kg once daily

Pediatric Dose (3 months–17 years):
Oral solution: 6 mg/kg (maximum dose 240 mg) once daily
Capsules (>33 kg): 200 mg once daily

Adolescent (≥18 years)/Adult dose:
Oral solution: 240 mg (24 mL) once daily
Capsules: 200 mg once daily

Dosing Recommendations for Combination Formulations

Truvada
Adult dose:
1 tablet once daily

Atripla
Adult dose:
1 tablet once daily

Selected Adverse Events

- Nausea, diarrhea
- Hyperpigmentation/skin discoloration on palms and/or soles, predominantly observed in nonwhite patients

Special Instructions

- Can be given without regard to food. Because Atripla contains EFV, administer the drug on an empty stomach.
- Oral solution can be kept at room temperatures up to 77°F (25°C) if used within 3 months; refrigerate for longer term storage.
- Screen patients for hepatitis B virus prior to use of FTC. Severe acute exacerbation of hepatitis can occur when FTC is discontinued; monitor hepatic function for several months after therapy with FTC is stopped.

Metabolism

- Limited metabolism: No CYP450 interactions.
- Renal excretion 86%: Competition with other compounds that undergo renal elimination.
- Decrease dosage in patients with impaired renal function. Consult manufacturer's prescribing information.
- Do not use Atripla (fixed-dose combination) in patients with CrCl <50 mL/min or in patients requiring dialysis.
- Do not use Truvada (fixed-dose combination) in patients with CrCl <30 mL/min or in patients requiring dialysis.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***
- *Other NRTIs:* Do not use in combination with lamivudine because of the similar resistance profiles and no additive benefit.
- *Renal elimination:* Competition with other compounds that undergo renal elimination (possible competition for renal tubular secretion). Drugs that decrease renal function could decrease clearance.

Major Toxicities:
- *More common:* Headache, insomnia, diarrhea, nausea, rash, and hyperpigmentation/skin discoloration (possibly more common in children).
- *Less common (more severe):* Neutropenia. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Exacerbations of hepatitis have occurred in HIV/HBV-coinfected patients changed from emtricitabine-containing to non-emtricitabine-containing regimens.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/FTC.html**).

Pediatric Experience: A single-dose pharmacokinetic study of emtricitabine liquid solution and capsules was performed in 25 HIV-infected children 2–17 years of age *[1]*. Emtricitabine was found to be well absorbed following oral administration, with a

mean elimination half-life of 11 hours (range 9.7 to 11.6 hours). Plasma concentrations in children receiving the 6 mg/kg emtricitabine once-daily dose were approximately equivalent to those in adults receiving the standard 200-mg dose.

Based on this dose-finding study, emtricitabine was given at a dose of 6 mg/kg once daily in combination with other antiretroviral drugs *[2-3]*. In a pediatric Phase II study, 71 antiretroviral-naïve children received emtricitabine plus stavudine and lopinavir/ritonavir while 45 treatment-experienced children were maintained on their initial regimens, but changed from lamivudine to emtricitabine *[3]*. Pharmacokinetic results were similar to the preceding dose-finding study *[1]*. Follow-up data extending to Week 96 indicated that 89% of the antiretroviral-naïve and 76% of the antiretroviral-experienced children maintained suppression of plasma HIV RNA <400 copies/mL (74% and 62%, respectively, at <50 copies/mL). Grade 3 or 4 laboratory abnormalities were found in 2.9% of the study population, and serious adverse events possibly related to emtricitabine were found to be 1.2% after 164 weeks of follow-up.

Emtricitabine was studied in PACTG P1021 at a dose of 6 mg/kg (maximum 240 mg/day as liquid or 200 mg/day as capsules) in combination with didanosine and efavirenz, all given once daily, in 37 antiretroviral-naïve HIV-infected children age 3 months to 21 years *[2]*. This regimen was well tolerated, and emtricitabine and didanosine concentrations met the desired target study concentrations. Eighty-five percent of subjects achieved HIV RNA <400 copies/mL and 72% maintained HIV RNA suppression to <50 copies/mL through 96 weeks of therapy. The median CD4 count rose by 329 cells/mm^3 at week 96.

A study in South Africa evaluated the pharmacokinetics of emtricitabine in 20 HIV-exposed infants age <3 months, given as 3 mg/kg once daily for two 4-day courses, separated by an interval of ≥2 weeks *[4]*. Emtricitabine exposure (AUC) in neonates receiving 3 mg/kg emtricitabine once daily was in the range of pediatric patients age >3 months receiving the recommended dose of 6 mg/kg once daily and adults receiving the once-daily recommended 200 mg emtricitabine dose (AUC approximately 10 hr*ug/mL). Emtricitabine AUC decreased with increasing age over the first 3 months of life, correlating with an increase in total body clearance of the drug. No safety issues were identified in this short pharmacokinetics study; however, extensive safety data are lacking in this age group.

Lamivudine (3TC/Epivir)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Oral Solution: 10 mg/mL (Epivir); 5 mg/mL (Epivir HBV[1])
Tablets: 150 mg (scored) and 300 mg (Epivir); 100 mg (Epivir HBV[1])
Combination Tablets:

- *With zidovudine (ZDV):* 150 mg 3TC + 300 mg ZDV (Combivir)
- *With abacavir (ABC):* 300 mg 3TC + 600 mg ABC (Epzicom)
- *With ZDV and ABC:* 150 mg 3TC + 300 mg ZDV + 300 mg ABC (Trizivir)

[1] Epivir HBV oral solution and tablets contain a lower amount of 3TC than Epivir oral solution and tablets. The formulation and dosing of 3TC in Epivir HBV are not appropriate for patients coinfected with HIV and HBV. If Epivir HBV used in HIV-infected patients, the higher dosage indicated for HIV therapy should be used as part of an appropriate combination regimen. The Epivir HBV tablet could be used in a child who requires a 100-mg 3TC dose for treatment of HIV infection.

Dosing Recommendations

Epivir (Oral Solution and Tablets)

Neonate/infant dose (<4 weeks) for prevention of transmission or treatment: 2 mg/kg twice daily

Pediatric dose (>4 weeks): 4 mg/kg (up to 150 mg) twice daily

Pediatric dosing for scored 150-mg tablet (weight ≥14 kg):

Weight (kg)	AM dose	PM dose	Total Daily Dose
14–21	½ tablet (75 mg)	½ tablet (75 mg)	150 mg
>21–<30	½ tablet (75 mg)	1 tablet (150 mg)	225 mg
≥30	1 tablet (150 mg)	1 tablet (150 mg)	300 mg

Adolescent (≥16 years)/Adult dose:
Body weight ≥50 kg: 150 mg twice daily or 300 mg once daily
Body weight <50 kg: 4 mg/kg (up to 150 mg) twice daily

Dosing Recommendations for Combination Formulations

Combivir
Adolescent (weight ≥30 kg)/Adult dose:
1 tablet twice daily

Trizivir
Adolescent (weight >40 kg)/Adult dose:
1 tablet twice daily

Epzicom
Adolescent (age >16 years)/Adult dose:
1 tablet once daily

Selected Adverse Events

- Minimal toxicity

Special Instructions

- Can be given without regard to food.
- Store oral solution at room temperature.
- Screen patients for HBV infection before starting therapy; exacerbation of hepatitis has been reported after discontinuation of 3TC. HIV/HBV-coinfected patients should have close clinical and laboratory monitoring for at least several months after stopping therapy with 3TC.

Metabolism

- Renal excretion – dosage adjustment required in renal insufficiency.
- Combivir and Trizivir (fixed-dose combination products) should not be used in patients with CrCl <50 mL/min, patients on dialysis, or patients with impaired hepatic function.

Drug Interactions (see also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.):

- *Renal elimination*: Drugs that decrease renal function could decrease clearance of lamivudine.
- *Other NRTIs:* Do not use lamivudine in combination with emtricitabine because of the similar resistance profiles and no additive benefit *[1]*.

Major Toxicities:

- *More common:* Headache, nausea.
- *Less common (more severe):* Peripheral neuropathy, pancreatitis, lipodystrophy/lipoatrophy.
- *Rare:* Increased liver enzymes. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/3TC.html**).

Pediatric Experience: Lamivudine has been studied in HIV-infected children alone and in combination with other antiretroviral drugs, and extensive data demonstrate that lamivudine appears safe and is associated with clinical improvement and virologic response *[2-17]*. Lamivudine is commonly used in HIV-infected children as a component of a dual-NRTI backbone, most often with zidovudine, as part of a combination antiretroviral drug regimen *[3-4, 6-7, 11-12, 14, 16-17]*. In one study, the NRTI background components of lamivudine/abacavir were superior to zidovudine/lamivudine or zidovudine/abacavir in long-term virologic efficacy *[18]*. Because of its safety profile and availability in a liquid formulation, lamivudine has been given to infants during the first 6 weeks of life *[11]*. Recently, weight band dosing recommendations for lamivudine have been developed *[19-20]*.

Few data are available regarding once-daily administration of lamivudine in children. The pharmacokinetics of once-daily versus twice-daily dosing of lamivudine (8 mg/kg once daily vs. 4 mg/kg twice daily) and abacavir (16 mg/kg once daily vs. 8 mg/kg twice daily) were evaluated in 20 HIV-infected children age 2–13 years in the PENTA-13 trial (all were stable on twice-daily therapy prior to randomization). The plasma AUC_{0-24} for both drugs was similar with once- and twice-daily administration, but trough concentrations were lower for both abacavir and lamivudine in younger children (age 2–6 years) receiving the once-daily regimen, as were peak (C_{max}) concentrations for lamivudine *[2]*. No major toxicities were noted, and there was improved acceptability of the once-daily dosing regimen *[2]*. Lamivudine undergoes intracellular metabolism to its active form, lamivudine triphosphate. In adolescents, the mean half-life of intracellular lamivudine triphosphate (17.7 hours) is considerably longer than that of unmetabolized lamivudine in plasma (1.5–2 hours). Intracellular concentrations of lamivudine triphosphate have been shown to be equivalent with once-daily and twice-daily dosing in adults and adolescents, supporting a recommendation for once-daily lamivudine dosing in adolescents ≥16 years and ≥50 kg *[21-22]*. More studies are needed to confirm that once-daily dosing of abacavir and lamivudine can be safely used in children.

Stavudine (d4T, Zerit)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Oral solution: 1 mg/mL
Capsules: 15 mg, 20 mg, 30 mg, and 40 mg
Generic: Stavudine capsules and solution have been approved by the FDA for manufacture and distribution in the United States.

Dosing Recommendations

Neonate/Infant dose (birth to 13 days):
0.5 mg/kg twice daily

Pediatric dose (14 days and up to 30 kg):
1 mg/kg twice daily

Adolescent (≥30 kg)/Adult dose:
30 to <60 kg: 30 mg twice daily
≥60 kg: 40 mg twice daily

Selected Adverse Events

- Peripheral neuropathy
- Fat maldistribution
- Pancreatitis
- Lactic acidosis with hepatic steatosis (higher incidence than with other NRTIs)
- Hyperlipidemia
- Rapidly progressive ascending neuromuscular weakness (rare)

Special Instructions

- Can be given without regard to food.
- Shake oral solution well. Keep refrigerated; will remain stable for 30 days.

Metabolism

- Renal excretion 50%. Decrease dose in renal dysfunction.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Renal elimination:* Drugs that decrease renal function could decrease stavudine clearance.
- *Other NRTIs*: Stavudine should not be administered in combination with zidovudine due to virologic antagonism.
- *Overlapping toxicities*: Combination of stavudine and didanosine is not recommended for initial therapy because of overlapping toxicities. Reported toxicities are more often reported in adults and include serious, even fatal, cases of lactic acidosis with hepatic steatosis with or without pancreatitis in pregnant women.

Major Toxicities:

- *More common:* Headache, gastrointestinal disturbances, skin rashes, hyperlipidemia, and fat maldistribution.
- *Less common (more severe):* Peripheral neuropathy and pancreatitis. Lactic acidosis and severe hepatomegaly with hepatic steatosis, including fatal cases, have been reported. The combination of stavudine with didanosine may result in enhanced toxicity (increased risk of fatal and nonfatal cases of lactic acidosis or pancreatitis), particularly in adults including pregnant women. This combination should not be used for initial therapy.
- *Rare:* Increased liver enzymes, rapidly progressive ascending neuromuscular weakness.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/d4T.html**).

Pediatric Experience: Stavudine has been studied in HIV-infected children as monotherapy and in combination with other antiretroviral drugs. Data from multiple pediatric studies of stavudine alone or in combination with other antiretrovirals demonstrate that stavudine appears safe and is associated with clinical and virologic response *[1-11]* In resource-limited countries, stavudine is frequently a component of initial HAART therapy in children in combination with nevirapine or efavirenz, often as a component of fixed-dose combinations not available in the United States. In this setting, reported outcomes from observational studies are good; data show substantial increases in the CD4 count and complete viral suppression in 50%–80% of treatment-naïve children *[12-15]*.

Early initiation of triple therapy with stavudine, didanosine, and nelfinavir was evaluated in 20 infants starting therapy at <3 months of age (median age at initiation, 2.5 months) *[1]*. Therapy was generally well tolerated; 7 infants (35%) experienced 11 events considered possibly related to study drugs, although only 3 such events (rash, diarrhea, and neutropenia) required drug modification. At least 1 episode of Grade 1 hypertriglyceridemia was observed in 19 of 20 (95%) infants; 9 of 12 (75%) infants with cholesterol measured after baseline had at least 1 episode of Grade 1 hypercholesterolemia. However, no infant had Grade 2 or higher triglyceride or cholesterol concentrations. Seventy percent of infants had incomplete viral suppression, which was associated with genotypic resistance mutations in 6 (30%) of these infants. However, only 2 infants developed resistance mutations to stavudine, and 1 of these infants had pre-existing TAMs present at baseline. Stavudine has been used as a component of a second regimen after treatment failure or as a replacement for zidovudine if the patient develops anemia. In a Phase II comparison study of stavudine and zidovudine, they were largely comparable in terms of safety and tolerability, although neutropenia occurred significantly less often among children receiving stavudine *[6]*. Stavudine is associated with a higher rate of adverse events than zidovudine in adults and children receiving combination therapy *[16-17]*. In a large pediatric natural history study (PACTG 219C), stavudine-containing regimens had a modest but significantly higher rate of clinical and laboratory toxicities than those containing zidovudine, with pancreatitis, peripheral neuropathy, and lipodystrophy/lipoatrophy (fat maldistribution) associated with stavudine *[17]*. Peripheral neuropathy is an important toxicity associated with stavudine but appears to be less common in children than in adults *[4, 6]*. Elevated hepatic transaminases are seen in about 11% and pancreatitis in 1% of adults enrolled in clinical trials of stavudine. In a small pediatric study of stavudine in combination with didanosine, no pharmacokinetic interactions were observed and there were no cases of peripheral neuropathy *[5]*. In PACTG 219C, peripheral neuropathy was recognized in 0.9% of children *[17]*. Lipodystrophy, and specifically lipoatrophy (loss of subcutaneous fat), are toxicities associated with the use of NRTIs, particularly stavudine, in adults and children *[18-20]*. Lipodystrophy developed in 28% of 39 children receiving stavudine, lamivudine, and nelfinavir after a median of 49 months of therapy with 9 demonstrating lipoatrophy *[10]*. Among 90 children receiving stavudine, lamivudine, and nevirapine or efavirenz, 65% developed lipodystrophy at 33 months *[21]*. Further research concerning body habitus changes associated with NRTI use in pediatric patients is ongoing. Lactic acidosis with hepatic steatosis, including fatal cases, has been reported with the use of nucleoside analogues, including stavudine, alone or in combination *[22-23]*. The combination of stavudine and didanosine in pregnant women has been associated with fatal lactic acidosis and should be used during pregnancy only if no other alternatives are available *[24]*. Many of these adverse events are believed to be due to mitochondrial toxicity resulting from inhibition of mitochondrial DNA polymerase gamma, with depletion of mitochondrial DNA demonstrated in fat, muscle, peripheral blood mononuclear cells, and other tissues *[22, 25-27]*. (For additional information on lactic acidosis see **Tables 17a–17h. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations**.)

Although the World Health Organization has chosen to limit the maximum dose of stavudine to 30 mg (WHO guidelines at www.who.int/hiv/art/ARTadultsaddendum.pdf), these guidelines support switching to another agent rather than lowering the dose of stavudine to reduce the risk of or to manage toxicity. This recommendation is based on the availability of alternative antiretroviral agents in the United States and concerns of some Panel members about suboptimal therapy with a lower dose of stavudine.

Tenofovir Disoproxil Fumarate (TDF, Viread)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Tablet: 300 mg

Combination tablets:

- *With emtricitabine (FTC)*: 200 mg FTC + 300 mg TDF (Truvada)
- *With FTC + efavirenz (EFV)*: 200 mg FTC + 600 mg EFV + 300 mg TDF (Atripla)

Dosing Recommendations

Neonate/Infant dose:

Not approved for use in neonates/infants.

Pediatric dose:

Not approved for use in children <12 years of age; only commercially available preparation is 300-mg tablet. Investigational dose of 8 mg/kg of body weight once daily in children <12 years of age provided a lower exposure than was observed in adults.

Adolescent (≥12 years and >35 kg) dose:

300 mg once daily

See text for concerns about decreased bone mineral density, especially in prepubertal patients and those in early puberty (Tanner stages 1 and 2).

Dosing Recommendations for Combination Formulations

Truvada

Adult dose:

1 tablet once daily

Atripla

Adult dose:

1 tablet once daily

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs

TDF in combination with didanosine (ddI)

ddI dose requires modification. See section on **ddI**.

TDF in combination with atazanavir (ATV)

Only ATV boosted with ritonavir (RTV) should be used in combination with TDF. See section on **ATV**.

Selected Adverse Events

- Asthenia, headache, diarrhea, nausea, vomiting, flatulence
- Renal insufficiency, Fanconi syndrome
- Decreased bone mineral density

Special Instructions

- TDF can be administered without regard to food, although absorption is enhanced when administered with a high-fat meal. It is recommended to administer Atripla on an empty stomach because it contains EFV.
- When coadministered, ddI delayed-release capsule formulation and TDF may be taken under fasted conditions or with a light meal.
- Screen patients for hepatitis B virus infection (HBV) prior to use of TDF. Severe acute exacerbation of HBV can occur when TDF is discontinued; monitor hepatic function for several months after therapy with TDF is stopped.

Metabolism

- Renal excretion.
- Dosing of TDF in patients with renal insufficiency: Decreased dosage should be used in patients with impaired renal function. Consult manufacturer's prescribing information for adjustment of dosage in accordance with creatinine clearance.
- Atripla (fixed-dose combination) should not be used in patients with CrCl <50 mL/min or in patients requiring dialysis.
- Truvada (fixed-dose combination) should not be used in patients with CrCl <30 mL/min or in patients requiring dialysis.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***):

- *Renal elimination:* Drugs that decrease renal function or compete for active tubular secretion could reduce clearance of tenofovir.
- *Other NRTIs:* Didanosine serum concentrations are increased when coadministered with tenofovir.
- *PIs:* Tenofovir decreases atazanavir plasma concentrations. In adults, the recommended dosing for atazanavir coadministered with tenofovir is atazanavir 300 mg with ritonavir 100 mg and tenofovir 300 mg, all as a single daily dose with food. Atazanavir without ritonavir should not be coadministered with tenofovir. In addition, atazanavir and lopinavir/ritonavir increase tenofovir concentrations and could potentiate tenofovir-associated toxicity.

Major Toxicities:

- *More common:* Nausea, diarrhea, vomiting, and flatulence.
- *Less common (more severe):* Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Tenofovir caused bone toxicity (osteomalacia and reduced bone density) in animals when given in high doses. Decreases in bone mineral density have been shown in both adults and children taking tenofovir for 48 weeks; the clinical significance of these changes is not yet known. Evidence of renal toxicity, including increases in serum creatinine, blood urea nitrogen, glycosuria, proteinuria, phosphaturia, and/or calciuria and decreases in serum phosphate has been observed. Numerous case reports of renal tubular dysfunction have been reported in patients receiving tenofovir; patients at increased risk of renal dysfunction should be closely monitored.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/TDF.html**).

Pediatric Experience: In a Phase I/II study of tenofovir for salvage therapy using an investigational 75-mg formulation in 18 heavily pretreated children and adolescents at the National Institutes of Health (NIH) *[1]*, the major toxicity attributable to tenofovir was a >6% decrease in bone mineral density (BMD) measured by dual-energy x-ray absorptiometry (DXA) scan in 5 of 15 (33%) children evaluated at Week 48. Two of the 5 children discontinued tenofovir at 48 weeks as required by the protocol and experienced partial or complete recovery of BMD by 96 weeks *[2]*. Among children with BMD decreases, the median Tanner score was 1 (range 1–3) and mean age was 10.2 years; for children who had no BMD decreases, the median Tanner score was 2.5 (range 1–4) and median age was 13.2 years *[2-3]*. In a second study of 6 patients at NIH using the commercially available 300-mg formulation of tenofovir, 2 prepubertal children experienced >6% BMD decreases. One of the 2 children, the smallest child in the study, experienced a 27% decrease in BMD, necessitating withdrawal of tenofovir from her antiretroviral therapy regimen. The child continued therapy without tenofovir and subsequently her BMD recovered *[4]* The data from both of these small studies suggest that tenofovir-related bone loss may be greater in less mature children (e.g., Tanner 1–2) than in those with more advanced development (Tanner ≥3), and other studies offer further support for this conclusion *[5-6]*.

It is also possible that the bone loss seen in the patients in the NIH studies *[1-4]* may have been associated with higher tenofovir exposures. All participants were treated with regimens that also contained ritonavir, which increases tenofovir exposure *[7-8]*. Although the median initial dose in the Phase I/II studies was 208 mg/m^2 (= 7.1 mg/kg), the administered dose varied from 161 to 256 mg/m^2 (3.7 to 10 mg/kg) *[1]*. Loss of bone mineral density at 48 weeks was associated with higher drug exposure (AUC) *[3]*. However, in this heavily pretreated cohort, the group with the best virologic response had statistically significantly higher AUC, suggesting that in salvage therapy tenofovir may have a relatively small therapeutic window, especially in children in Tanner stages 1–2.

In contrast to the NIH studies, an Italian study showed no effect of tenofovir on BMD in pediatric patients on stable therapy with undetectable viral load who were switched from stavudine and PI-containing regimens to tenofovir/lamivudine/efavirenz *[9]*. The different results may be explained by different patient populations, differences in concurrent medication use, and tenofovir dosing. The patients in the Italian study *[9-11]* included older participants (up to age 18 years), had greater height and weight *z* scores, and the majority were in middle to late puberty or postpubertal. The NIH study involved heavily treatment experienced patients in need of salvage therapy while the Italian study evaluated BMD in a potentially healthier population of patients who were required to have long-lasting viral suppression prior to the switch in therapy. Finally, because the patients in the Italian study received tenofovir in the absence of ritonavir and were administered fractions of tenofovir pills to provide lower doses, the tenofovir concentrations experienced by the Italian patients may have been lower than those seen in the NIH patients. No BMD studies have been reported in treatment-naïve children who initiate therapy with tenofovir.

No significant renal disease was seen with tenofovir therapy in either of the 2 small NIH studies or in the Italian study. In 6/159 (3.7%) children with HIV-1 treated with tenofovir in the Collaborative HIV Pediatric Study (CHIPS) in the United Kingdom and Ireland, renal toxicity leading to discontinuation of tenofovir was reported *[12]*. All 6 of those patients were taking didanosine and lopinavir/ritonavir in addition to tenofovir, and the interaction of didanosine and tenofovir *[13]* or the boosting of tenofovir exposure by concurrent use of lopinavir/ritonavir *[7]* may have caused this toxicity. Possible tenofovir-associated nephrotoxicity manifest as Fanconi syndrome, reduced creatinine clearance, and diabetes insipidus has been reported in a child receiving tenofovir as a component of salvage therapy including lopinavir/ritonavir and didanosine for 1 year *[14]*, and irreversible renal failure has been reported in an adolescent treated with tenofovir without didanosine *[15]*. Increased urinary beta-2 microglobulin suggesting proximal renal tubular damage was identified in 12 of 44 (27%) children treated with tenofovir

compared with 2 of 48 (4%) children not treated with tenofovir *[16]*. An observational cohort study of 2,102 children with HIV in the United States suggested an increased risk of renal disease (increased creatinine or proteinuria) in children treated with tenofovir-containing combination antiretroviral therapy *[17]*. However, no significant decrease in calculated glomerular filtration rate was found in 27 HIV-infected children treated with tenofovir for 96 weeks *[10]*. Lipid profiles improved significantly after the switch from stavudine and PI-containing regimens to tenofovir/lamivudine/efavirenz *[11]*.

The NIH study, using a 75-mg tablet formulation of tenofovir in treatment-experienced children and adolescents 6–18 years of age, showed that a median dose of 208 mg/m^2 of body surface area (range 161–256 mg/m^2 body surface area) resulted in a median single dose AUC and C_{max} that were 34% and 27% lower, respectively, compared with values reported in adults administered a daily dose of 300 mg *[1, 18]*. Renal clearance of tenofovir was approximately 1.5-fold higher in children than previously reported in adults, possibly explaining the lower systemic exposure *[1]*. Steady-state tenofovir exposures were higher but still less than those seen in adults and may reflect the concomitant treatment with ritonavir, which boosts tenofovir plasma concentrations. Lower than anticipated tenofovir exposure was also found in young adults (median age 23 years) treated with atazanavir/ritonavir plus tenofovir *[19]*. The clinical impact of these low drug exposures is unknown, but in the NIH study, lower single-dose and steady-state AUC were associated with inferior virologic outcome *[3]*. The CHIPS cohort used a target dose of 8 mg/kg, but 18% were dosed at >120% of the target and 37% at less than 80%.

In the Italian study, which only enrolled patients with undetectable viral load on current therapy, all HIV-infected children remained clinically stable and virologically suppressed after the change to a tenofovir-containing regimen *[11]*. In the NIH "salvage" study, plasma HIV RNA concentrations ($\log_{10}$ copies/mL) decreased from a median pretreatment concentration of 5.4 $\log_{10}$ copies/mL to 4.21 $\log_{10}$ copies/mL after 48 weeks of therapy *[3]*. HIV RNA was <400 copies/mL in 6/16 (37.5%) participants and <50 copies/mL in 4/16 (25%) participants at 48 weeks. In the CHIPS cohort 115 patients had outcome data available *[12]*. Viral load decreased to <50 copies/mL at 12 months in 38% of patients starting tenofovir for the first time; in 50% on first-line therapy; 39% of those on second-line therapy; and 13% of patients on third-line or greater therapy *[12]*.

In March 2010, the FDA approved the use of tenofovir in adolescents ≥12 years of age and weighing ≥35 kg based upon data from Gilead study 321, a randomized, placebo-controlled trial of tenofovir or placebo plus an optimized background regimen in 87 treatment-experienced adolescents between 12 and <18 years of age in Brazil and Panama *[20-21]*. No difference in viral load response was seen between the 2 groups. Subgroup analyses suggest this lack of response may have been due to imbalances in viral susceptibility to the optimized background regimens between the 2 groups. Importantly, impaired bone accrual was seen in the tenofovir group, manifest by declining BMD *z* scores over 48 and 96 weeks. In addition, 6 of 33 (18%) participants in the tenofovir arm experienced a >4% decline in absolute lumbar spine BMD in 48 weeks compared with only 1 of 33 (3%) participants in the placebo arm *[20-21]*. Limited pharmacokinetic data were reported from 8 participants and suggested that tenofovir exposures were higher than those seen in the NIH study, but no data on correlation of tenofovir exposure with BMD loss were provided.

Given this potential for BMD loss, some experts recommend obtaining a DXA prior to the initiation of tenofovir therapy and approximately 6 months after start of tenofovir, especially in prepubertal patients and those early in puberty (Tanner stages 1 and 2). However, in view of the potential cost and difficulty in obtaining pediatric DXA in some settings, other experts try to avoid using tenofovir in prepubertal patients and those in early puberty, especially for initial therapy. Despite the ease of use of a once-daily drug and the efficacy of tenofovir, this potential for BMD loss during the important period of rapid bone accrual in adolescence is concerning and favors judicious use of tenofovir in this age group. There is still an urgent need for more research to develop appropriate pediatric formulations and to identify the safest uses of tenofovir in children and adolescents.

An investigational liquid formulation has been studied in children 2–8 years of age; a tenofovir dose of 8 mg/kg resulted in tenofovir exposure similar to that observed in adults receiving a tenofovir dose of 300 mg, but this formulation had poor palatability and was not developed further *[22]*. A powder formulation is also under investigation. An investigational dose of 8 mg/kg of body weight once daily in children <12 years of age provided a lower exposure than was observed in adults, and the FDA has recommended that a higher dose be evaluated in this age group *[21]*.

Zidovudine (ZDV, AZT, Retrovir)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Capsules: 100 mg
Tablets: 300 mg
Syrup: 10 mg/mL
Concentrate for injection/for intravenous infusion: 10 mg/mL
Generic: ZDV capsules, tablets, and solution are approved by the FDA for manufacture and distribution in the United States.
Combination tablets:

- *With lamivudine (3TC)*: 300 mg ZDV + 150 mg 3TC (Combivir)
- *With 3TC + abacavir (ABC)*: 300 mg ZDV + 150 mg 3TC + 300 mg ABC (Trizivir)

Dosing Recommendations

Premature infant dose for prevention of transmission or treatment (standard neonate dose may be excessive in premature infants):
1.5 mg/kg of body weight (intravenous) or 2 mg/kg of body weight (oral) every 12 hours, increased to every 8 hours at 2 weeks of age (neonates ≥30 weeks gestational age) or at 4 weeks of age (neonates <30 weeks gestational age)

Neonate/Infant dose (<6 weeks) for prevention of transmission or treatment:
Oral: 2 mg/kg of body weight every 6 hours
Intravenous: 1.5 mg/kg of body weight every 6 hours

Pediatric dose (6 weeks to <18 years):
Body surface area dosing:
Oral: 180–240 mg/m^2 of body surface area every 12 hours or 160 mg/m^2 every 8 hours

Weight-based dosing:

Body Weight	Twice-Daily Dosing*
4 kg to <9 kg	12 mg/kg
9 kg to <30 kg	9 mg/kg
≥30 kg	300 mg

*Three times daily dosing is approved but rarely used in clinical practice.

Adolescent (≥18 years)/Adult dose:
200 mg three times a day or 300 mg twice daily

Dosing Recommendations for Combination Formulations

Combivir
Adolescent (weight ≥30 kg)/Adult dose:
1 tablet twice daily

Trizivir
Adolescent (weight ≥40 kg)/Adult dose:
1 tablet twice daily

Selected Adverse Events

- Bone marrow suppression: macrocytic anemia or neutropenia
- GI intolerance, headache, insomnia, asthenia
- Lactic acidosis with hepatic steatosis

Special Instructions

- Can be given without regard to food.
- Substantial granulocytopenia or anemia may necessitate interruption of therapy until marrow recovery is observed; use of erythropoietin, filgrastim, or transfusion may be necessary in some patients.

Metabolism

- Metabolized to AZT glucuronide (GAZT), which is renally excreted.
- Dosage adjustment required in renal insufficiency.
- Decreased dosing may be required in patients with hepatic impairment.
- Combivir and Trizivir (fixed-dose combination products) should not be used in patients with CrCl <50 mL/min, patients on dialysis, or patients with impaired hepatic function.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)**:**

- *Other NRTIs:* Should not be administered in combination with stavudine due to virologic antagonism.
- *Bone marrow suppressive/cytotoxic agents including ganciclovir, interferon alpha, and ribavirin:* May increase the hematologic toxicity of zidovudine.
- *Doxorubicin:* Use should be avoided.

Major Toxicities:

- *More common:* Hematologic toxicity, including granulocytopenia and anemia. Headache, malaise, nausea, vomiting, and anorexia.
- *Less common (more severe):* Myopathy (associated with prolonged use), myositis, and liver toxicity. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Fat maldistribution.
- *Rare:* Increased risk of hypospadias after first-trimester exposure to zidovudine observed in one cohort study.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/ZDV.html**).

Pediatric Experience: Zidovudine was the first NRTI studied in adult and pediatric clinical trials and the first antiretroviral agent approved for treatment of HIV infection. Data from multiple pediatric studies of zidovudine alone or in combination with other antiretrovirals demonstrate that zidovudine appears safe and is associated with clinical improvement and virologic and immunologic effects *[1-16]*.

Perinatal trial PACTG 076 established that a zidovudine prophylactic regimen given during pregnancy, labor, and to the newborn reduced the risk of perinatal HIV transmission by nearly 70% *[17]*. Recommended neonatal zidovudine dosing for prevention of mother-to-child transmission of HIV is 2 mg/kg orally every 6 hours or 1.5 mg/kg intravenously every 6 hours for those unable to receive oral dosing. Although not FDA approved, twice-daily dosing (4 mg/kg every 12 hours) is sometimes prescribed when concerns about adherence exist, but the efficacy of this approach for prevention of mother-to-child transmission has not been evaluated. Pharmacokinetic studies, such as PACTG 331, have shown that dose adjustments are necessary for premature infants due to decreased zidovudine clearance compared with term newborns of similar postnatal ages *[2, 6]*. Resistance mutations were shown to be present in 5 of 17 (29%) newborns born to mothers who received zidovudine during pregnancy *[18]*.

Overall, zidovudine pharmacokinetics in pediatric patients >3 months of age are similar to those in adult patients. The manufacturer's recommended oral dose in pediatric patients 6 weeks to 12 years of age is 160 mg per meter^2 of body surface area every 8 hours or 240 mg per meter^2 of body surface area every 12 hours, in combination with other antiretroviral agents, although the recommended dose for adults is 300 mg twice daily. Recently, weight band dosing has also been approved *[19]*. Zidovudine undergoes intracellular metabolism to its active form, zidovudine triphosphate. Although the mean half-life of intracellular zidovudine triphosphate (9.1 hours) is considerably longer than that of unmetabolized zidovudine in plasma (1.5 hours), once-daily zidovudine dosing is not recommended because of low intracellular zidovudine triphosphate concentrations seen with 600-mg once-daily dosing in adolescents *[20]*. Zidovudine has good central nervous system (CNS) penetration (cerebrospinal fluid-to-plasma concentration ratio = 0.68) and has been used in children with HIV-related CNS disease *[1]*.

NON-NUCLEOSIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS

Efavirenz (EFV, Sustiva)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Capsules: 50 mg and 200 mg
Tablets: 600 mg
Combination tablets:
- *with emtricitabine (FTC) and tenofovir disoproxil fumarate (TDF)*:
  200 mg FTC + 300 mg TDF + 600 mg EFV (Atripla)

Dosing Recommendations

Neonate/Infant dose:
Not approved for use in neonates/infants.

Pediatric dose:
Children <3 years of age:
There are currently no data available on the appropriate dosage for children <3 years of age.

Children ≥3 years and ≥10 kg:
Administer EFV once daily:

Weight (kg)	EFV dose (mg)*
10–<15	200
15–<20	250
20–<25	300
25–<32.5	350
32.5–<40	400
≥40	600

***** The dose in mg could be dispensed in any combination of capsule strengths; dose represents the maximum recommended EFV dose for each weight band.

Adolescent (≥40 kg)/Adult dose:
600 mg once daily

Dosing Recommendations for Combination Formulations

Atripla
Atripla should not be used in pediatric patients <40 kg where the EFV dose would be excessive.

Adult dose:
One tablet once daily

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs

Atazanavir (ATV), **fosamprenavir (FPV)**, **indinavir (IDV)**, **lopinavir/ritonavir (LPV/r)**, and **maraviroc (MVC)** used in combination with EFV may require dosage adjustment or addition of RTV. See appropriate drug section.

Selected Adverse Events

- Rash
- Central nervous system symptoms
- Increased transaminases
- False-positive with some cannabinoid and benzodiazepine tests
- Teratogenic
- Lipohypertrophy

Special Instructions

- Administer EFV on an empty stomach, preferably at bedtime. The relative bioavailability of EFV was increased by 50% (range 11%–126%) following a high fat meal. Because there is no information on the safety of EFV when given above the recommended dose, avoid administration with a high fat meal due to the potential for increased absorption.
- Administer Atripla on an empty stomach.
- Capsules may be opened and added to liquids or small amounts of food.
- Bedtime dosing is recommended, particularly during the first 2 to 4 weeks of therapy, to improve tolerability of central nervous system side effects.

Metabolism

- Metabolized by cytochrome P450, 2B6, and 3A4. CYP 3A4 inducer/inhibitor (more inducer than inhibitor).
- Dosing of EFV in patients with hepatic impairment: No recommendation is currently available; use with caution in patients with hepatic impairment.
- Adult dose of Atripla in patients with renal impairment: Because Atripla is a fixed-dose combination product, it should not be used in patients with creatinine clearance of <50 mL/minute or in patients on dialysis.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism*: Mixed inducer/inhibitor of cytochrome P450 3A4 enzymes; concentrations of concomitant drugs can be increased or decreased depending on the specific enzyme pathway involved. There are multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Skin rash, increased transaminase levels. Central nervous system abnormalities (e.g., somnolence, insomnia, abnormal dreams, confusion, abnormal thinking, impaired concentration, amnesia, agitation, depersonalization, hallucinations, euphoria) primarily reported in adults.
- *Rare*: In cynomolgus monkeys, prenatal efavirenz exposure has been associated with central nervous system congenital abnormalities in infant monkeys. Based on these data and retrospective reports in humans of an unusual pattern of severe central nervous system defects in five infants after first-trimester exposure to efavirenz-containing regimens (three meningomyelocoeles and two Dandy-Walker malformations), efavirenz has been classified as FDA Pregnancy Class D (positive evidence of human fetal risk). Efavirenz use in the first trimester of pregnancy should be avoided. Women of childbearing potential should undergo pregnancy testing and be counseled about the risk of efavirenz to the fetus and need to avoid pregnancy before initiating and during efavirenz therapy.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/EFV.html**).

Pediatric Experience: Efavirenz has been studied in HIV-infected children in combinations of efavirenz plus NRTIs or efavirenz plus NRTIs plus a PI (nelfinavir or lopinavir/ritonavir) *[1-17]*. An open label study (PACTG 382) of efavirenz combined with nelfinavir and 1 or 2 NRTIs was performed in 57 NNRTI- and PI-naïve pediatric patients, some as young as 3 years of age *[11]*. In an intent-to-treat analysis, 76% of children had plasma HIV RNA concentrations <400 copies/mL and 63% had HIV RNA concentrations <50 copies/mL at 48 weeks of therapy. The median times to achieve those concentrations were 4 and 20 weeks, respectively. Therefore, children with detectable HIV RNA (>50 copies/mL by the ultra-sensitive RNA assay) after 1 month of therapy continued to accrue some virologic benefit through 5 months of treatment with this regimen *[10]*. Long-term virologic suppression with once-daily efavirenz therapy in combination with emtricitabine and didanosine was reported in 37 treatment-naïve children, 3–18 years of age, participating in PACTG 1021 *[8]*. Eighty-five percent of subjects were able to achieve HIV-RNA <400 copies/mL and 72% maintained HIV-RNA suppression <50 copies/mL through 96 weeks of therapy.

A study of a liquid formulation of efavirenz in 19 HIV-infected children 3–9 years of age has been reported *[12]*. A 20% higher dose of efavirenz liquid formulation resulted in pharmacokinetic AUC values that were similar to those observed with efavirenz capsules. Limited pharmacokinetic data in children <3 years of age or who weigh <13 kg have shown that it is difficult to achieve target trough concentrations in this age group even with very high (>30 mg/kg) doses of this investigational liquid formulation *[18]*. Thus, efavirenz is not recommended for use in children <3 years of age at this time and no liquid formulation is commercially available. Additional studies are required to determine the appropriate dose of efavirenz in infants and young children.

Efavirenz metabolism is controlled by enzymes that are polymorphically expressed and result in large between patient variability in efavirenz exposure. CYP 2B6 is the primary enyzme for efavirenz metabolism and pediatric patients with the 516 T/T or G/T genotype have reduced metabolism and higher efavirenz levels compared with those with the G/G genotype *[19-20]*. Additional variant CYP 2B6 alleles and variant CYP 2A6 alleles have been found to influence efavirenz concentrations in adults *[21-22]*.

Long-term HIV RNA suppression has been associated with maintenance of trough efavirenz concentrations >1 mcg/mL in adults *[23]*. Early HIV RNA suppression in children has also been seen with higher drug concentrations. Higher efavirenz troughs of 1.9 mcg/mL were seen in subjects with HIV RNA ≤400 copies/mL versus efavirenz troughs of 1.3 mcg/mL in subjects with detectible virus (>400 copies/mL) *[3]*. In a West African pediatric study, ANRS 12103, early reduction in viral load (12 weeks) was greater in children with efavirenz C_{min} >1.1 mcg/mL or AUC >51 mcg*h/mL *[24]*. Even with the use of FDA-approved pediatric dosing, efavirenz concentrations can be suboptimal *[19, 24-25]*, so that some experts recommend therapeutic drug monitoring when using efavirenz and possibly using higher doses in young children, especially in select clinical situations such as virologic rebound or lack of response in an adherent patient. In 1 study that adjusted the efavirenz

dose in response to measurement of the AUC, the administered efavirenz dose median was 13 mg/kg (367 mg/m^2) and the range was from 3 to 23 mg/kg (69 to 559 mg/m^2) *[3]*. A pharmacokinetic study in 20 children age 10 to 16 years treated with the combination of lopinavir/ritonavir 300 mg/m^2 twice daily plus efavirenz 350 mg/m^2 once daily showed adequacy of the lopinavir trough values but suggested that the efavirenz trough was lower than pharmacokinetic targets, and the authors recommend that higher doses of efavirenz might be needed when these drugs are used together *[16]*. Therapeutic drug monitoring might be considered when using efavirenz in combinations with potentially complex drug interactions.

The toxicity profile for efavirenz differs for adults and children. In adults, a central nervous system (CNS) complex of confusion, agitation, sleep disturbance, nightmares, hallucinations, or other symptoms has been reported in >50% of patients *[26]*. These symptoms usually occur early in treatment and rarely require drug discontinuation but sometimes occur or persist for months. Bedtime efavirenz dosing appears to decrease the occurrence and severity of these neuropsychiatric side effects. In several studies, the incidence of such side effects was correlated with efavirenz plasma concentrations and occurred more frequently in patients with higher concentrations *[23, 27-30]*. In patients with pre-existing psychiatric conditions, efavirenz should be used cautiously for initial therapy. Adverse CNS effects occurred in 14% of children receiving efavirenz in clinical studies *[11]* and in 30% of children with efavirenz concentrations >4 mcg/mL *[20]*. The principal side effect of efavirenz in children is rash, which was seen in up to 40% of children, compared with 27% of adults. The rash is usually maculopapular, pruritic, and mild to moderate in severity and rarely requires drug discontinuation. Onset is typically in the first 2 weeks of treatment *[11]*. Although severe rash and Stevens-Johnson syndrome have been reported, this is rare. Other reported adverse events in adults and children include diarrhea, nausea, and increased transaminases including liver failure *[31]*. There are insufficient data to recommend substituting nevirapine for efavirenz following either rash or hepatotoxicity *[32]*.

Efavirenz should be used with caution in adolescent women of childbearing age because of the risk of teratogenicity *[33]*. See ***Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*** *[34]*. Many clinicians choose alternative drugs for use in sexually active adolescent women in whom contraception use is sometimes erratic and the risk of unintended pregnancy is high.

Etravirine (ETR, Intelence, TMC 125)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Tablets: 100 mg

Dosing Recommendations

Neonate/Infant dose:
Not approved for use in neonates/infants.

Pediatric dose:
Not approved for use in children.

Adult dose (ARV-experienced patients):
200 mg (two 100 mg tablets) twice daily following a meal

Selected Adverse Events

- Nausea
- Rash including Stevens-Johnson syndrome
- Hypersensitivity reactions have been reported, characterized by rash, constitutional findings, and sometimes organ dysfunction, including hepatic failure

Special Instructions

- Always administer ETR following a meal; area under the curve (AUC) is decreased by about 50% when taken on an empty stomach.
- Tablets are sensitive to moisture; store at room temperature (59–86°F) in original container with desiccant.
- Patients unable to swallow tablets may disperse the tablets in a small amount of water. Once dispersed, instruct patients to stir the dispersion well and consume it immediately. The glass should be rinsed with water several times and each of the rinses completely swallowed to ensure that the entire dose is consumed.
- Dosing of ETR in patients with hepatic impairment: No dosage adjustment is necessary for patients with mild-to-moderate hepatic insufficiency. No dosing information is available for patients with severe hepatic impairment.
- Dosing of ETR in patients with renal impairment: No dose adjustments are required in patients with renal impairment.

Metabolism

- Metabolism by cytochrome P450: inducer of CYP3A4 and inhibitor of CYP2C9, CYP2C19. Substrate for CYP3A4, 2C9, and 2C19. Also inhibitor of P-glycoprotein.
- Multiple drug interactions (see below).

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism*: Etravirine is an inducer of CYP3A4; an inhibitor of CYP2C9 and CPY2C19; and a substrate for 3A4, 2C9, and 2C19. Etravirine is also an inhibitor of P-glycoprotein.
- There are multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.
- Etravirine should not be coadministered with the following antiretrovirals: tipranavir/ritonavir, fosamprenavir/ritonavir, amprenavir/ritonavir, ritonavir, unboosted PIs, nevirapine, or efavirenz.

Major Toxicities:

- *More common:* Nausea, diarrhea, mild rash. Rash occurs most commonly in the first 6 weeks of therapy. Rash generally resolves after 1 to 2 weeks on continued therapy. A history of NNRTI-related rash does not appear to increase the risk of developing rash with etravirine. However, patients who have a history of severe rash with prior NNRTI use should not receive etravirine.
- *Less common:* Severe rash including Stevens-Johnson syndrome, hypersensitivity reactions (including constitutional findings and sometimes organ dysfunction including hepatic failure), and erythema multiforme have been reported. Discontinue etravirine immediately if signs or symptoms of severe skin reactions or hypersensitivity reactions develop (including severe rash or rash accompanied by fever, general malaise, fatigue, muscle or joint aches, blisters, oral lesions, conjunctivitis, facial edema, hepatitis, eosinophilia). Clinical status including liver transaminases should be monitored and

appropriate therapy initiated. Delay in stopping etravirine treatment after the onset of severe rash may result in a life-threatening reaction. It is recommended that patients who have a prior history of severe rash with nevirapine or efavirenz not receive etravirine.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/ETR.html**).

Pediatric Experience: The pharmacokinetics, safety, and efficacy of etravirine in pediatric patients have not been established. There is limited pediatric experience and pediatric trials are under way. Recently reported are the results of a Phase I dose finding study involving 21 children with virologic suppression on a stable lopinavir/ritonavir-containing regimen *[1]*. Etravirine therapy was added for 1 week and pharmacokinetic sampling and analysis were performed. The findings from this trial were used to determine the dose in the Phase II trial in pediatric patients that is currently under way. At this time data are insufficient to recommend a pediatric dose and further studies are warranted to determine the pharmacokinetics, safety, and efficacy of etravirine in children.

Recently reported was an analysis of genotypic and phenotypic HIV resistance profiles in 35 children from a Ugandan clinic with clinical failure of a first-line regimen containing an NNRTI other than etravirine *[2]*. Reduced etravirine susceptibility (fold-change >2.9) was found based on phenotypic analysis in 35% of samples.

Nevirapine (NVP, Viramune)

For more information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/**

Formulations

Tablets: 200 mg
Suspension: 10 mg/mL

Dosing Recommendations

Neonate/Infant dose (<14 days):
When used for prophylaxis of mother-to-child transmission of HIV see **Perinatal Guidelines**.[†]
Treatment dose not defined for infants ≤14 days of age.

Pediatric dose (≥15 days):
(See note below about initiation of therapy.)

<8 years:
200 mg/m^2 of body surface area/dose (maximum dose 200 mg) twice daily

≥8 years: 120–150 mg/m^2 of body surface area/dose (maximum dose 200 mg) twice daily

When adjusting the dose for a growing child, the mg dose need not be decreased as the child reaches 8 years; rather, the mg dose is left static to achieve the appropriate mg-per-m^2 dosage as the child grows, as long as there are no untoward effects.

NVP is initiated at a lower dose and increased in a stepwise fashion to allow induction of cytochrome P450 metabolizing enzymes, which results in increased clearance of the drug. The occurrence of rash is diminished by this stepwise increase in dose. Initiate therapy with the age-appropriate dose once daily for the first 14 days of therapy. If there is no rash or untoward effect, at 14 days of therapy increase to the age-appropriate dose administered twice daily. The total daily dose should not exceed 400 mg.

Adolescent/Adult dose:
200 mg twice daily

Initiate therapy with 200 mg given once daily for the first 14 days. Increase to 200 mg administered twice daily if there is no rash or other untoward effects.

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs

NVP in combination with lopinavir/ritonavir (LPV/r)
A higher dose of LPV/r may be needed. See **LPV/r** section.

Selected Adverse Events

- Rash, including Stevens-Johnson syndrome
- Symptomatic hepatitis, including fatal hepatic necrosis
- Severe systemic hypersensitivity syndrome with potential for multisystem organ involvement and shock

Special Instructions

- Can be given without regard to food.
- May be administered concurrently with didanosine (ddI).
- NVP-associated skin rash usually occurs within the first 6 weeks of therapy. If rash occurs during the initial 14-day lead-in period, do not increase dose until rash resolves (see *Major Toxicities*).
- If NVP dosing is interrupted for >7 days, NVP dosing should be restarted with once-daily dosing for 14 days, followed by escalation to the full, twice-daily regimen.
- Most cases of NVP-associated hepatic toxicity occur during the first 12 weeks of therapy; frequent clinical and laboratory monitoring, including liver function tests, is important during this time period. However, about one-third of cases occurred after 12 weeks of treatment, so continued periodic monitoring of liver function tests is needed. In some cases, patients presented with nonspecific prodromal signs or symptoms of hepatitis and rapidly progressed to hepatic failure. Patients with symptoms or signs of hepatitis should have liver function tests performed. NVP should be permanently discontinued and not restarted in patients who develop clinical hepatitis or hypersensitivity reactions.
- Shake suspension well and store at room temperature.

Metabolism

- Metabolized by cytochrome P450 (3A inducer); 80% excreted in urine (glucuronidated metabolites).
- Dosing of NVP in patients with renal failure receiving hemodialysis: An additional dose of NVP should be given following dialysis.
- Dosing of NVP in patients with hepatic impairment: NVP should not be administered to patients with moderate or severe hepatic impairment.

[†] Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism*: Induces hepatic cytochrome P450 including 3A (CYP3A) and 2B6; autoinduction of metabolism occurs in 2 to 4 weeks, with a 1.5–2-fold increase in clearance. There is potential for multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions. Nevirapine should not be coadministered to patients receiving atazanavir (with or without ritonavir).

Major Toxicities:

(*Note:* These are seen with continuous dosing regimens, not single-dose nevirapine prophylaxis.)

- *More common:* Skin rash (some severe and requiring hospitalization; some life-threatening, including Stevens-Johnson syndrome and toxic epidermal necrolysis), fever, nausea, headache, and abnormal hepatic transaminases. Nevirapine should be permanently discontinued and not restarted in children or adults who develop severe rash, rash with constitutional symptoms, or rash with elevated hepatic transaminases. Nevirapine-associated skin rash usually occurs within the first 6 weeks of therapy. If rash occurs during the initial 14-day lead-in period, do not increase dose until rash resolves. However, the risk of developing nevirapine resistance with extended lead-in dosing is unknown and is a concern that must be weighed against the patient's overall ability to tolerate the regimen and the current antiviral response. Nevirapine should be discontinued immediately and not restarted in patients who develop severe rash, a rash accompanied by constitutional symptoms (i.e., fever, oral lesions, conjunctivitis, or blistering), or rash accompanied by elevated hepatic transaminases.
- *Less common (more severe):* Severe, life-threatening, and in rare cases fatal hepatotoxicity, including fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure (these are less common in children than adults). The majority of cases occur in the first 12 weeks of therapy; may be associated with rash or other signs or symptoms of hypersensitivity reaction. Risk factors for nevirapine-related hepatic toxicity in adults include baseline elevation in serum transaminase levels, hepatitis B or C infection, female gender, and higher CD4 count at time of therapy initiation (CD4 count >250 cells/mm^3 in adult females and >400 cells/mm^3 in adult males). Hypersensitivity reactions have been reported, including but not limited to severe rash or rash accompanied by fever, blisters, oral lesions, conjunctivitis, facial edema, muscle or joint aches, general malaise, and significant hepatic abnormalities. Nevirapine should be permanently discontinued and not restarted in children or adults who develop symptomatic hepatitis, severe transaminase elevations, or hypersensitivity reactions.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/NVP.html**).

Pediatric Experience: Nevirapine has been studied in HIV-infected children in combination with NRTIs or with NRTIs and a PI *[1-9]*. Combination therapy with nevirapine, zidovudine, and didanosine in young infected infants was associated with sustained viral suppression in a small number of children *[6]*. A description of 15 infants initiating nevirapine-based antiretroviral treatment younger than 66 days of age in Belgium reported that complete viral suppression (<400 copies/mL) was achieved in 11 (73%) infants *[10]*. A larger study, PACTG 356, treated infants and young children with 3 different nevirapine-containing regimens: zidovudine/lamivudine/nevirapine, zidovudine/lamivudine/abacavir/nevirapine, or zidovudine/lamivudine/nevirapine/nelfinavir *[4]*. Twenty-four percent of 17 infants treated with the 3-drug regimen had viral suppression to <400 copies/mL HIV RNA, compared with 10 of 17 (41%) and 15 of 18 (83%), respectively, of infants treated with 4 drugs. Children who started therapy younger than 3 months of age had a better virologic outcome compared with children who started at an older age (3.5–24 months). PACTG 377 randomized 181 PI- and NNRTI-naïve mild to moderately immune suppressed children to 1 of 4 combination treatment regimens. All of the regimens contained stavudine and a PI (either ritonavir or nelfinavir); 3 of the 4 regimens also included nevirapine as part of combination therapy. Children in the nevirapine-containing arms experienced moderate or worse skin rash more frequently than did children not receiving nevirapine. Those children receiving a 4-drug regimen containing both nevirapine and a PI had a significantly greater increase in CD4 cell count from baseline to Week 24 than children receiving other regimens *[9]*. A study of 212 children in Cambodia treated with NNRTI-based combination therapy (82% nevirapine and 18% efavirenz) reported 156 of 212 children (73.6%) having undetectable viral load (<400 copies/mL) after 12 months of treatment. Only 2 children switched regimens due to intolerability of nevirapine *[1]*. In PACTG 403, 41 children with prior NRTI experience were randomized to receive stavudine/nelfinavir/nevirapine or didanosine/nelfinavir/ritonavir. After 48 weeks of therapy, only 28% (5/18) of those still on the nevirapine-inclusive regimen had viral suppression to <400 copies/mL compared with 65% (11/17) of children on the ritonavir-based treatment. The changes in CD4 percentage and the rates of toxicities were similar for both regimens. Three children developed nevirapine-related rashes leading to discontinuation of study treatment *[2]*.

In infants and children previously exposed to single-dose nevirapine for prevention of mother-to-child transmission (PMTCT), nevirapine-based antiretroviral therapy is less likely than lopinavir/ritonavir-based ART to control virus load. In a small, nonrandomized study in Botswana, 6-month virologic and immunologic responses were compared between 15 SD nevirapine-exposed and 15 -unexposed infants who initiated nevirapine-based antiretroviral treatment at a mean age of 8 months (range 2–33 months) in follow-up from a PMTCT study *[11]*. Only 34% of those with a history of exposure had an undetectable viral load (<400 copies/mL) compared with 91% of the unexposed cohort. CD4 percentage was also significantly lower in the exposed group compared with the unexposed group, 23% versus 31%, respectively. In contrast, in a study in Uganda, in which children with SD nevirapine exposure started nevirapine-based treatment at an older age of 1.6 years, there was no difference in response to therapy between children with and without prior SD nevirapine exposure *[12]*. In a large randomized clinical trial, P1060, 153 children (mean age 0.7 years) previously exposed to nevirapine for perinatal prophylaxis were treated with zidovudine plus lamivudine plus the randomized addition of nevirapine versus lopinavir/ritonavir. At 24 weeks post-randomization, 24% of children in the zidovudine/lamivudine/nevirapine arm reached a virologic endpoint (virologic failure [VF] defined as <1 log decrease in HIV RNA in Weeks 12–24 or HIV RNA >400 copies/mL at Week 24) compared with 7% in the zidovudine/lamivudine/lopinavir/ritonavir arm, p = 0.0009. When all primary endpoints were considered, including viral failure, death, and treatment discontinuation, the PI arm remained superior because 40% of children in the nevirapine arm met a primary endpoint versus 22% for the lopinavir/ritonavir arm, p = 0.027. Based on these findings the Data and Safety Monitoring Board (DSMB) recommended discontinuing enrollment in this cohort. Enrollment into the comparison study of nevirapine versus lopinavir/ritonavir in children 6–36 months of age not previously exposed to nevirapine is ongoing *[13]*.

Body surface area has traditionally been used to guide nevirapine dosing for infants and young children. It is important to avoid underdosing of nevirapine because a single point mutation may confer NNRTI resistance to both nevirapine and efavirenz. Younger children (≤8 years of age) have higher apparent oral clearance than older children and require a higher dosage to achieve equivalent drug exposure compared with children >8 years of age. *[6-7]*. Because of this, it is recommended that dosing for children younger than 8 years of age be 200 mg/m^2 of body surface area per dose (maximum dose 200 mg) administered twice daily. For children 8 years or older, the recommended dose is 120 mg/m^2 of body surface area per dose (maximum dose 200 mg) administered twice daily. When adjusting the dose in a growing child, the milligram dose need not be decreased (from 200 mg/m^2 to 120 mg/m^2) as the child reaches 8 years; rather, the milligram dose is left static as long as there are no untoward effects, and the dose is allowed to achieve the appropriate mg/m^2 dosage as the child grows. Some practitioners dose nevirapine at 150 mg/m^2 of body surface area every 12 hours (maximum of 200 mg per dose) regardless of age, as recommended in the FDA-approved product label.

PROTEASE INHIBITORS

Atazanavir (ATV, Reyataz)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Capsules: 100 mg, 150 mg, 200 mg, and 300 mg

Dosing Recommendations

Neonate/Infant dose:
Not approved for use in neonates/infants. ATV should not be administered to neonates due to the risks associated with hyperbilirubinemia (kernicterus).

Pediatric dose:
There are insufficient data to recommend dosing in all children younger than 6 years of age or for treatment-experienced children weighing less than 25 kg.

For children 6–18 years of age:

Weight (kg)	Once-Daily Dose*
Treatment-Naïve ** Children Only	
15 to <25 kg	ATV 150 mg + RTV 80 mg, both once daily with food
Both Treatment-Naïve and Treatment-Experienced Children	
25 to <32 kg	ATV 200 mg + RTV 100 mg, both once daily with food
32 to <39 kg	ATV 250 mg + RTV 100 mg, both once daily with food
≥39 kg	ATV 300 mg + RTV 100 mg, both once daily with food

*Higher doses than those currently recommended may be required for some patients. See discussion under pediatric experience.
**There are insufficient data to recommend this dose in treatment-experienced children weighing less than 25 kg.

For treatment-naive pediatric patients who do not tolerate ritonavir (RTV): **Atazanavir boosted with RTV is preferred for children and adolescents.** Current FDA-approved prescribing information does not recommend unboosted ATV in children younger than 13 years of age. If unboosted ATV is used in adolescents, higher doses than those used in adults may be required to achieve target drug levels (see pediatric experience section).

Adolescent (≥16–21 years)/Adult dose:
Antiretroviral-naïve patients:
ATV 300 mg + RTV 100 mg **or** ATV 400 mg once daily with food

Antiretroviral-experienced patients:
ATV 300 mg + RTV 100 mg, both once daily with food

Selected Adverse Events

- Indirect hyperbilirubinemia
- Prolonged PR interval, first degree symptomatic AV block in some patients
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia
- Nephrolithiasis

Special Instructions

- Administer ATV with food to enhance absorption.
- Unboosted ATV does not appear to increase cholesterol or triglyceride levels. However, ATV boosted with RTV may be associated with lipid abnormalities.
- Because ATV can prolong the electrocardiogram PR interval, use with caution in patients with pre-existing cardiac conduction system disease or with other drugs known to prolong the PR interval (e.g., calcium channel blockers, beta-blockers, digoxin, verapamil).
- ATV absorption is dependent on low gastric pH and when administered with medications that alter gastric pH, special dosing information is indicated. When administered with buffered didanosine (ddI) formulations or antacids, ATV should be taken at least 2 hours before or 1 hour after antacid or ddI administration.
- Individuals with HBV or HCV infections and individuals with marked elevations in transaminases prior to treatment may be at increased risk of further elevations in transaminases or hepatic decompensation.

Metabolism

- ATV is a substrate and inhibitor of CYP3A4 and an inhibitor of CYP1A2, CYP2C9, and UGT1A1.
- Dosing of ATV in patients with hepatic impairment: ATV should be used with caution in patients with mild-to-moderate hepatic impairment; consult manufacturer's prescribing information for adjustment of dosage in patients with moderate impairment. ATV should not be used in patients with severe hepatic impairment.
- Dosing of ATV in patients with renal impairment: No dose adjustment is required for patients with renal impairment. However, ATV should not be given to treatment-experienced patients with end-stage renal disease on hemodialysis.

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs	
ATV in combination with efavirenz (EFV) in therapy-naïve patients only **Adult dose:** ATV 400 mg + RTV 100 mg + EFV 600 mg, all once daily but at separate times Although ATV/r should be taken with food, EFV should be taken on an empty stomach, preferably at bedtime. EFV should not be used with ATV (with or without RTV) in treatment-experienced patients because EFV decreases ATV exposure. ***ATV in combination with tenofovir (TDF)*** **Adult dose:** ATV 300 mg + RTV 100 mg + TDF 300 mg, all once daily with food Only RTV-boosted ATV should be used in combination with TDF because TDF decreases ATV exposure.	

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents****.)*:

- *Metabolism*: Atazanavir is both a substrate and an inhibitor of the CYP3A4 enzyme system and has significant interactions with drugs highly dependent on CYP3A4 for metabolism. Atazanavir also competitively inhibits CYP1A2 and CYP2C9. There is potential for multiple drug interactions. Atazanavir inhibits the glucuronidation enzyme uridine diphosphate glucoronosyltransferase (UGT1A1). Atazanavir is a weak inhibitor of CYP2C8.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.
- *NRTIs*: Tenofovir decreases atazanavir plasma concentrations. Only ritonavir-boosted atazanavir should be used in combination with tenofovir.
- *NNRTIs*: Efavirenz, etravirine, and nevirapine decrease atazanavir plasma concentrations significantly. Nevirapine and etravirine should not be coadministered to patients receiving atazanavir (with or without ritonavir). Efavirenz should not be coadministered with atazanavir in treatment-experienced patients but may be used in treatment-naïve adults with atazanavir 400 mg plus ritonavir boosting.
- *Absorption*: Atazanavir absorption is dependent on low gastric pH and when administered with medications that alter gastric pH, special dosing information is indicated. No information is available in children when dosing atazanavir with medications that alter gastric pH.

Guidelines for dosing atazanavir with antacids, H2 receptor antagonists, and proton pump inhibitors in adults are as follows:

- *Antacids*: Antacids and buffered medications (including buffered didanosine formulations) decrease atazanavir concentrations if administered at the same time; atazanavir should be administered 2 hours before or 1 hour after these medications.
- *H2-Receptor Antagonists (unboosted atazanavir in treatment-naïve patients)*: H2-receptor antagonists are expected to decrease atazanavir concentrations by interfering with absorption. Atazanavir 400 mg should be administered at least 2 hours before or at least 10 hours after a dose of the H2-receptor antagonist (no single dose should exceed a dose comparable to famotidine 20 mg and total daily dose should not exceed a dose comparable to famotidine 40 mg).
- *H2-Receptor Antagonists (boosted atazanavir in treatment-naïve or -experienced patients)*: H2-receptor antagonists are expected to decrease atazanavir concentrations by interfering with absorption. Dose recommendations for H2-receptor antagonists are either a ≤40-mg dose equivalent of famotidine twice daily (treatment-naïve patients) or a ≤20-mg dose equivalent of famotidine twice daily (treatment-experienced patients). Dose (ATV 300 mg + RTV 100 mg) should be administered simultaneously with and/or ≥10 hours after the dose of H2-receptor antagonist.
- *H2-Receptor Antagonists (boosted atazanavir with tenofovir)*: In treatment-experienced patients, if tenofovir is used with H2-receptor antagonists, an increased dose of atazanavir should be given: 400 mg ATV + 100 mg RTV + 300 mg TDF.
- *Proton-pump Inhibitors:* Coadministration of atazanavir with proton-pump inhibitors is expected to substantially decrease atazanavir plasma concentrations and decrease therapeutic effect. Dose recommendations for therapy-naïve patients are

≤20-mg dose equivalent of omeprazole taken approximately 12 hours prior to boosted atazanavir (ATV 300 mg + RTV 100 mg). Coadministration of atazanavir with proton-pump inhibitors is not recommended in treatment-experienced patients.

Major Toxicities:

- *More common:* Indirect hyperbilirubinemia that can result in jaundice or icterus but is not a marker of hepatic toxicity. Headache, fever, arthralgia, depression, insomnia, dizziness, nausea, vomiting, diarrhea, and paresthesias.
- *Less common:* Prolongation of PR interval of electrocardiogram. Abnormalities in AV conduction generally limited to first-degree AV block, but with rare reports of second-degree AV block. Rash, generally mild to moderate, but in rare cases includes life-threatening Stevens-Johnson syndrome. Fat maldistribution and lipid abnormalities may be less common than with other PIs. However, the addition of ritonavir to atazanavir is associated with lipid abnormalities but to a lesser extent than with other boosted PIs.
- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, and elevation in serum transaminases. Nephrolithiasis. Hepatotoxicity (patients with hepatitis B or C are at increased risk).

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/ATV.html**).

Pediatric Experience: IMPAACT/PACTG 1020A is an ongoing Phase II international trial of atazanavir with and without ritonavir in children 3 months to 19 years of age. In addition to capsules, a powder formulation of atazanavir is also under study. In this trial, atazanavir plasma concentration monitoring is used to guide therapy and establish optimum starting doses. Both ritonavir-boosted and -unboosted atazanavir regimens are used for treatment-naïve and -experienced patients. In the trial, protocol-defined AUC, C_{min}, and C_{max} targets were deliberately set at levels higher than those achieved in the early adult atazanavir trials to compensate for the wide interpatient variability in pharmacokinetics values seen in adults in those trials; the pharmacokinetic targets were the same for atazanavir given with and without ritonavir boosting. In IMPAACT/PACTG 1020A, dosing for each age cohort was targeted to achieve AUC ≥30 μg*hour/mL and C24 ≥60 ng/mL.

To date, the results of the IMPAACT/PACTG 1020A trial in children and adolescents indicate that in the absence of ritonavir boosting, atazanavir can achieve protocol-defined pharmacokinetic targets, but only when used at higher doses of atazanavir (on a mg-per-kg body weight or mg-per-meter^2 body surface area basis) than doses currently recommended in adults. In IMPAACT/PACTG 1020A, children >6 and <13 years of age required atazanavir dosing of 520 mg per meter^2 of body surface area per day of atazanavir capsule formulation to achieve pharmacokinetic targets. For older adolescents, doses required were greater than the adult approved dose of 400 mg atazanavir given without ritonavir boosting once daily: adolescents age >13 years required ATV dosing of 620 mg per meter^2 of body surface area per day *[1-2]*. In this study, the AUCs for the unboosted arms were similar in the ritonavir-boosted atazanavir groups but the C_{max} was higher and C_{min} lower for the unboosted arms. Median doses of atazanavir in mg/m^2 both with and without ritonavir boosting from IMPAACT/PACTG 1020A are outlined in the following table. When dosing unboosted atazanavir in pediatric patients, therapeutic drug monitoring is recommended to ensure that adequate atazanavir plasma concentrations have been achieved. A minimum target trough concentration for atazanavir is 150ng/mL *[3]*. Higher target trough concentrations may be required in PI-experienced patients.

Summary of Dosing Information Obtained from IMPAACT/PACTG 1020A *[2]*

Age range (years)	Was ATV given with RTV boosting?	ATV median dose in mg/m^2*	ATV median dose in mg*
6–13 years	No	509	475
6–13 years	Yes	208	200
>13 years	No	620	900
>13 years	Yes	195	350

*Data satisfied protocol-defined AUC/pharmacokinetic parameters and met all acceptable safety targets. These doses differ from those recommended by the manufacturer. Therapeutic drug monitoring was used to determine patient-specific dosing in this trial.

A summary of the efficacy results from IMPAACT/PACTG 1020A is included in the prescribing information: In 99 patients (6 years to >18 years of age) treated with either boosted or unboosted atazanavir, the overall proportions of antiretroviral-naïve and -experienced patients with HIV RNA <50 copies/mL at Week 24 were 59% (24/41) and 24% (14/58), respectively. The median increase from baseline in absolute CD4 count at 20 weeks of therapy was 171 cells/mm^3 and 116 cells/mm^3 in antiretroviral-

naïve patients and antiretroviral-experienced patients, respectively *[4]*. Overall, 11 of 129 (8.5%) patients enrolled had a bilirubin >5 times the upper limit of normal. Asymptomatic electrocardiogram (EKG) abnormalities were observed in a small number of patients: 1 patient had a Grade 3 QTC prolongation, 9 had Grade 2 PR or HR changes, and 3 had Grade 3 PR prolongations. No significant changes in serum cholesterol or triglycerides were observed during 48 weeks of therapy in 63 children receiving unboosted atazanavir in combination with 2 NRTIs *[5]*.

In a small single site study, 23 pediatric patients (median age 16) on combination antiretroviral therapy were switched to a once-daily ritonavir-boosted atazanavir (ATV/r)-containing regimen for virologic failure (12) or for treatment simplification (11) *[6]*. Twenty of the patients had previously received protease inhibitor-based regimens with the median number of 2 atazanavir mutations. Patients received atazanavir doses lower than those currently recommended and many patients received concomitant therapy with tenofovir and/or didanosine; both drugs are known to have pharmacokinetic interactions with atazanavir. In this study, atazanavir plasma concentrations were measured at 12–15 hours after dosing: 6 patients had undetectable levels at multiple time points, and considerable interpatient variability in plasma atazanavir concentrations was noted. Four of the 13 patients with previously undetectable viral loads experienced virologic failure and 6 of the 12 patients who previously had virologic failure achieved undetectable viral loads. This study provides further evidence of the large interpatient variability in atazanavir pharmacokinetics in children, the need for higher doses, and the potential benefit of therapeutic drug monitoring to ensure that adequate atazanavir concentrations are achieved.

Darunavir (DRV, Prezista)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Tablets: 75 mg, 150 mg, 400 mg, and 600 mg

Dosing Recommendations

Darunavir should not be used without ritonavir (RTV).

Neonate/Infant dose:
Not approved for use in neonates/infants.

Pediatric dose:
DRV should not be used in pediatric patients <3 years of age.

3 to <6 years:
Safety and efficacy have not been established.

6 to <18 years and ≥20 kg:

Weight	Dose (both twice daily* with food)
≥20 to <30 kg	DRV 375 mg + RTV 50 mg (0.6 ml of 80 mg/ml)
≥30 to <40 kg	DRV 450 mg + RTV 60 mg (0.8 ml of 80 mg/ml)
≥40 kg	DRV 600 mg + RTV 100 mg

* Do not use once-daily dosing in pediatric patients.

Adolescent (age ≥18 years)/Adult dose (treatment naïve):
DRV 800 mg + RTV 100 mg, both once daily with food

Adolescent (age ≥18 years)/Adult dose (treatment experienced):
DRV 600 mg + RTV 100 mg, both twice daily with food

Selected Adverse Events

- Skin rash (DRV has a sulfonamide moiety. Stevens-Johnson syndrome and erythema multiforme have been reported.)
- Hepatotoxicity
- Diarrhea
- Nausea
- Headaches
- Possible increased bleeding in patients with hemophilia
- Hyperlipidemia, transaminase elevation, hyperglycemia
- Fat maldistribution

Special Instructions

- Administer DRV with food, which increases AUC and Cmax by 30%. Drug exposure is not significantly altered by the number of calories and fat content of the meal.
- DRV contains a sulfa moiety. The potential for cross sensitivity between DRV and other drugs in the sulfonamide class is unknown. Use DRV with caution in patients with known sulfonamide allergy.
- Pediatric dosing requires administration of multiple 75-mg or 150-mg tablets to achieve the recommended doses of 375 mg or 450 mg depending on weight band. Pill burden may have a negative effect on adherence.
- Store at room temperature (25ºC or 77ºF).

Metabolism

- CYP 3A4 inhibitor and substrate.
- Dosing in patients with hepatic impairment: DRV is primarily metabolized by the liver. There are no data for dosing adult patients with varying degrees of hepatic impairment; caution should be used when administering DRV to such patients. DRV is not recommended in patients with severe hepatic impairment.
- Dosing in patients with renal impairment: No dose adjustment is required in patients with moderate renal impairment (CrCl 30–60 mL/min). There are no pharmacokinetic data in patients with severe renal impairment or end-stage renal disease.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism:* Darunavir is primarily metabolized by cytochrome P450 3A4. Ritonavir inhibits CYP3A4, thereby increasing the plasma concentration of darunavir. There is the potential for multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Diarrhea, nausea, vomiting, abdominal pain, headache, and fatigue.
- *Less common:* Skin rash, including erythema multiforme and Stevens-Johnson syndrome, have been reported. Fever and elevated hepatic transaminases have been reported. Lipid abnormalities.

- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs. Hepatic dysfunction, particularly in patients with underlying risk factors (e.g., hepatitis B or hepatitis C virus coinfection, baseline elevation in transaminases).

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/DRV.html**).

Pediatric Experience: FDA approval for use in children 6 years of age and older was based upon a randomized, open-label, multicenter study that enrolled 80 treatment-experienced pediatric subjects age 6–<18 years and weighing ≥20 kg. Patients were stratified according to their weight and received darunavir/ritonavir plus background therapy consisting of at least 2 non-PI antiretroviral drugs *[1]*. This was a 2-part Phase II trial to evaluate the pharmacokinetics and tolerance of darunavir/ritonavir in children. In Part I, a weight-adjusted dose of darunavir 9–15 mg/kg and ritonavir 1.5–2.5 mg/kg twice daily, equivalent to the standard adult dose of darunavir/ritonavir 600/100 mg twice daily, resulted in inadequate drug exposure in the pediatric population studied with AUC_{24h} of 81% and C_{0h} of 91% of the corresponding adult pharmacokinetic (PK) parameters. A pediatric dose 20%–33% higher than the scaled adult dose was needed to achieve drug exposure similar to that found in adults and was the dose selected for Part II of the study. The higher dose used for the safety and efficacy evaluation was darunavir 11–19 mg/kg and ritonavir 1.5–2.5 mg/kg twice daily. This resulted in AUC_{24h} of 123,276 ng*h/ml (range 71,850–201,520) and C_{0h} of 3,693 ng/mL (range 1,842–7,191), 102% and 114% of the respective PK values in adults. Patients were stratified by body weight: 20 to <30 kg and 30 to <40 kg. Doses were all given twice daily and were adjusted when patients changed weight categories. After the 2-week PK evaluation all patients were allowed to switch to ritonavir 100-mg capsules if desired to avoid the use of liquid oral ritonavir.

Based on the findings in the safety and efficacy portion of the study, weight band doses of darunavir/ritonavir were as follows: 375/50 mg twice daily for body weight 20 to <30kg, 450/60 mg twice daily for 30 to <40 kg, and 600/100 mg twice daily for ≥40 kg. Note that 27 of the 80 participants in this portion of the study switched from the ritonavir liquid formulation to ritonavir 100-mg capsules. The 80 subjects had a median age of 14 (range 6 to <18 years), 71% were male, 54% white, 30% black, 9% Hispanic, and 8% other. The mean baseline plasma HIV-1 RNA was 4.64 $\log_{10}$ copies/mL, and the median baseline CD4 cell count was 330 cells/mm^3 (range: 6–1,505 cells/mm^3). Overall, 38% of pediatric subjects had baseline plasma HIV RNA ≥100,000 copies/mL, 79% had previous use of at least 1 NNRTI, and 96% had previously used at least 1 PI. The subjects had a median of 11 PI mutations. Only 6% of subjects discontinued the study before Week 48 (only 1 for an adverse event). The proportion of pediatric subjects with HIV RNA <400 copies/mL and <50 copies/mL at Week 48 was 59% and 48%, respectively. The mean CD4 cell count increase from baseline was 110 cells/mm^3.

Although darunavir is approved for once-daily dosing in antiretroviral-naïve adults, it should not be used once daily in children because of more rapid clearance and absence of pediatric data.

Fosamprenavir (FPV, Lexiva)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Oral suspension: 50 mg/mL
Tablets: 700 mg FPV calcium

Dosing Recommendations

Neonate/Infant dose: Not approved for use in neonates/infants.

Pediatric dose (2–18 years of age): Dosing regimen depends on whether patient is antiretroviral naïve or antiretroviral experienced. Once-daily dosing is not recommended for pediatric patients.

Antiretroviral-naïve patients (2–5 years):
Unboosted (without ritonavir [RTV])
FPV 30 mg/kg (maximum dose 1,400 mg) twice daily

Antiretroviral-naïve patients (≥6 years):
Unboosted (without RTV)
FPV 30 mg/kg (maximum dose 1,400 mg) twice daily
or
Boosted with RTV
FPV 18 mg/kg (maximum dose 700 mg) + RTV 3 mg/kg (maximum dose 100 mg), both twice daily

Antiretroviral-experienced patients (≥6 years):
Boosted with RTV
FPV 18 mg/kg (maximum dose 700 mg) + RTV 3 mg/kg (maximum dose 100 mg), both twice daily

When administered without RTV, the adult regimen of FPV tablets (FPV 1,400 mg twice daily) can be used for patients weighing ≥47 kg **or** when administered with RTV, the adult regimen of 700 mg FPV tablets + 100 mg RTV, both given twice daily, can be used in patients weighing ≥39 kg. RTV pills can be used in patients weighing ≥33 kg.

Adolescent (>18 years)/Adult dose:
Dosing regimen depends on whether the patient is antiretroviral naïve or experienced.

Antiretroviral-naïve patients:
Unboosted (without RTV), twice-daily regimen
FPV 1,400 mg twice daily
Boosted with RTV, twice-daily regimen
FPV 700 mg + RTV 100 mg, both twice daily
Boosted with RTV, once-daily regimen
FPV 1,400 mg + RTV 200 mg, both once daily **or**
FPV 1,400 mg + RTV 100 mg, both once daily

Protease inhibitor-experienced patients:
FPV 700 mg + RTV 100 mg, both twice daily

Once-daily administration of FPV + RTV is not recommended in PI-experienced patients.

Selected Adverse Events

- Diarrhea, nausea, vomiting
- Skin rash
- Headache
- Hyperlipidemia, hyperglycemia
- Nephrolithiasis
- Transaminase elevation
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

Special Instructions

- Tablets can be taken with or without food. Adults should take the suspension without food. Pediatric patients can take the suspension with food.
- Patients taking antacids or buffered formulations of didanosine (ddI) should take FPV at least 1 hour before or after antacid or ddI use.
- FPV contains a sulfonamide. The potential for cross sensitivity between FPV and other drugs in the sulfonamide class is unknown. FPV should be used with caution in patients with sulfonamide allergy.
- Shake oral suspension well prior to use. Refrigeration is not required.

Metabolism

- The prodrug FPV is rapidly and almost completely hydrolyzed to amprenavir (APV) by cellular phosphatases in the gut as it is absorbed.
- APV is a cytochrome P450 3A4 inhibitor, inducer, and substrate.
- Dosage adjustment in patients with hepatic insufficiency is recommended.

Fosamprenavir (FPV, Lexiva)

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs	
FPV in combination with efavirenz (EFV) Only FPV boosted with RTV should be used in combination with EFV. **Adult dose:** *Twice-daily regimen* FPV 700 mg + RTV 100 mg, both twice daily + EFV 600 mg once daily *PI-naïve patients only, once-daily regimen* FPV 1,400 mg + RTV 300 mg + EFV 600 mg, all once daily ***FPV in combination with maraviroc (MVC)*** **Adult dose:** See **MVC** section for dosing of FPV with MVC.	

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- Fosamprenavir has the potential for multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Vomiting, nausea, diarrhea, perioral paresthesias, headache, rash, and lipid abnormalities.
- *Less common (more severe):* Life-threatening rash, including Stevens-Johnson syndrome, in <1% of patients. Fat maldistribution, neutropenia, and elevated serum creatinine kinase levels.
- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, hemolytic anemia, elevation in serum transaminases, angioedema, and nephrolithiasis.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/APV_FPV.html**).

Pediatric Experience: In June 2007, fosamprenavir suspension was approved for use in pediatric patients. The approval was based on two open label studies in pediatric patients 2–18 years of age *[1-2]*. Both studies enrolled treatment-experienced and treatment-naïve subjects. In one study, twice-daily dosing regimens (with or without ritonavir) were evaluated in combination with other antiretroviral agents. Overall, fosamprenavir was well tolerated and effective in suppressing viral load and increasing CD4 cell count. In one trial, after 24 weeks 67% of PI-naïve subjects in the fosamprenavir group (age 2–5 years only) and 70% of PI-naïve subjects in the fosamprenavir/ritonavir group (age 5–18 years) but only 57% of PI-experienced subjects in the fosamprenavir/ritonavir group (age 5–18 years) achieved HIV RNA <400 copies/mL. Median increases in CD4 percent at Week 24 occurred in all groups and ranged from 4% to 8% *[2]*. In a second trial, once-daily fosamprenavir/ritonavir was studied. Following information about suboptimal response to once-daily dosing in treatment-experienced adults, pediatric patients were allowed to switch to twice-daily therapy; however, few patients (10 of 69) opted to switch to twice-daily therapy (median time to switch: 45 weeks). At 24 and 48 weeks of therapy, HIV RNA was <400 copies/mL in 66% and 47% among PI-naïve subjects, respectively, and 57% and 43% among PI-experienced subjects, respectively. Median increase in CD4 percent at Week 48 was 10% for PI-naïve and 5% for PI-experienced subjects *[1]*. These data were insufficient to support a once-daily dosing regimen of ritonavir-boosted fosamprenavir in children and hence once-daily dosing is not recommended for pediatric patients. Toxicities from these trials included vomiting (3%–7%), diarrhea (3%–4%), and nausea (3%–4%).

A trial of pediatric patients taking the parent compound (amprenavir) demonstrated that the drug was relatively well tolerated with mild-to-moderate toxicity related mainly to the gastrointestinal system *[3]*.

Indinavir (IDV, Crixivan)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Capsules: 100 mg, 200 mg, and 400 mg

Dosing Recommendations

Neonate/Infant dose:
Not approved for use in neonates/infants.
Should not be administered to neonates due to the risks associated with hyperbilirubinemia (kernicterus).

Pediatric dose:
Not approved for use in children.

Investigational dose:
500 mg/m^2 of body surface area every 8 hours

Adolescent/Adult dose:
800 mg every 8 hours

IDV in combination with ritonavir (RTV)
Adolescent/Adult dose:
800 mg IDV + 100 or 200 mg RTV every 12 hours

Selected Adverse Events

- Nephrolithiasis
- GI intolerance, nausea
- Indirect hyperbilirubinemia
- Hyperlipidemia
- Headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, alopecia, and hemolytic anemia
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

Special Instructions

- Administer on an empty stomach 1 hour before or 2 hours after a meal (or administer with a light meal). When given in combination with RTV, meal restrictions are no longer necessary.
- Adequate hydration is required to minimize risk of nephrolithiasis (≥48 oz of fluid daily in adult patients).
- If coadministered with didanosine (ddI), give ≥1 hour apart on an empty stomach.
- Capsules are sensitive to moisture; store at room temperature (59–86ºF) in original container with desiccant.

Metabolism

- Cytochrome P450 3A4 inhibitor and substrate.
- Decreased dosage should be used in patients with mild-to-moderate hepatic impairment (recommended dose for adults is 600 mg IDV every 8 hours). No dosing information is available for children with any degree of hepatic impairment or for adults with severe hepatic impairment.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism*: Cytochrome P450 3A4 (CYP3A4) is the major enzyme responsible for metabolism. There is potential for multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Nausea, abdominal pain, headache, metallic taste, dizziness, asymptomatic hyperbilirubinemia (10%), lipid abnormalities, pruritis, and rash. Nephrolithiasis/urolithiasis with indinavir crystal deposits: cumulative frequency is higher in children (29%) than in adults (12.4%).
- *Less common (more severe):* Fat redistribution.
- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, acute hemolytic anemia, and hepatitis (life-threatening in rare cases).

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/IDV.html**).

Pediatric Experience: Indinavir has not been approved by the FDA for use in the pediatric population. It has been studied in HIV-infected children as monotherapy and in combination with other antiretroviral drugs in dosage ranges of 300–600 mg per

meter^2 of body surface area given every 8 hours *[1-16]*. Data in children indicate that a pediatric dose of 500–600 mg indinavir per meter^2 of body surface area given every 8 hours results in peak blood concentrations similar to those in adults; however, a significant proportion of children had trough indinavir concentrations less than the 0.1 mg/L value associated with virologic efficacy in adults *[3, 10]*.

Ritonavir-boosted indinavir has also been studied in children. One study evaluated 500 mg indinavir per meter^2 of body surface area plus 100 mg ritonavir per meter^2 of body surface area twice daily in 4 children 1–10 years of age; in 1 child, this resulted in high concentrations of both drugs and was accompanied by symptoms of renal toxicity *[11]*. Another study evaluated the pharmacokinetics of 400 mg indinavir per meter^2 of body surface area plus 125 mg ritonavir per meter^2 of body surface area twice daily in 14 children; this dosing resulted in AUC and trough concentrations similar to those observed with standard doses of indinavir /ritonavir in adults (800 mg indinavir/100 mg ritonavir twice daily), although the peak concentration was slightly decreased *[1]*. Clinical results from that trial demonstrated that virologic efficacy was good but that 4 of 21 patients developed nephrolithiasis and the overall rate of side effects and intolerance to the regimen was high *[5]*. In a study from Thailand a lower dose of indinavir (median 234 mg per meter^2) with low dose ritonavir resulted in low trough levels of indinavir in 2 of 12 children *[17]*.

In a study of 21 children receiving PI-containing antiretroviral therapy, all patients receiving indinavir experienced substantial increases in their triglyceride concentrations but no significant increases in total cholesterol occurred; blood glucose concentrations were not significantly different between baseline and follow-up evaluations *[18]*. In a study of 25 children toxicities observed with indinavir included flank pain and headache (16%), renal dysfunction (16%), hematuria (12%), and skin rash (12%) *[10]*. The cumulative frequency of nephrolithiasis is substantially higher in children (29%) than in adults (12.4%, range across clinical trials 4.7%–34.4%) *[19]*. This is likely due to the difficulty in maintaining adequate hydration in children. In a study of indinavir in 54 children, 13% developed hematuria *[9]* Children treated with indinavir also have a high cumulative incidence of sterile leukocyturia, which may be accompanied by elevations in serum creatinine in the absence of clinical symptoms of nephrolithiasis *[13]*. A large analysis of more than 2,000 HIV-infected children from PACTG 219 demonstrated a hazard ratio of 1.7 for the risk of renal dysfunction among children receiving combination antiretroviral therapy with indinavir *[20]*.

Lopinavir/Ritonavir (LPV/r, Kaletra)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Pediatric oral solution: 80 mg/20 mg LPV/r/mL (contains 42.4% alcohol by volume)
Pediatric tablets: 100 mg/25 mg LPV/r
Tablets: 200 mg/50 mg LPV/r

Dosing Recommendations

Neonate/Infant dose:
Infants <14 days: No data on appropriate dose or safety. Should not be used in preterm infants in the immediate postnatal period.

Infants 14 days to 6 months: Once-daily dosing is **not** recommended.

The recommended dose of the oral solution is 300 mg/75 mg LPV/r per m^2 of body surface area or 16 mg/4 mg LPV/r per kg of body weight twice daily. Do not administer LPV/r with efavirenz (EFV), nevirapine (NVP), fosamprenavir (FPV), or nelfinavir (NFV) in infants <6 months of age.

Use of 300 mg/75 mg LPV/r per m2 of body surface area in infants <6 months of age is associated with lower LPV trough levels than those found in adults; infants should be evaluated and LPV dosing adjusted for growth at frequent intervals (see discussion).

Pediatric dose (>6 months to 18 years):
*For individuals **not** receiving concomitant EFV, NVP, FPV, or NFV:*

Once-daily dosing is **not** recommended.

Body surface area dosing:
230 mg/57.5 mg LPV/r/m^2 of body surface area per dose twice daily

Weight-based dosing:
<15 kg: 12 mg/3 mg LPV/r/kg body weight per dose twice daily

≥15 kg to 40 kg: 10 mg/2.5 mg LPV/r/kg body weight per dose twice daily

≥40 kg: 400 mg/100 mg LPV/r per dose twice daily

Dosing for 100 mg/25 mg LPV/r Pediatric Tablets for Children/Adolescents **Without** Concomitant EFV, NVP, FPV, or NFV.

Body Weight (kg)	Body Surface Area (m^2)*	Recommended Number of 100 mg/25 mg LPV/r Tablets Given Twice Daily
15 to 25 kg	≥0.6 to <0.9 m^2	2
>25 to 35 kg	≥0.9 to <1.4 m^2	3
>35 kg	≥1.4 m^2	4 (or two 200 mg/50 mg LPV/r adult tablets)

*Oral solution is available for children age 6 months to 18 years with a

Selected Adverse Events

- GI intolerance, nausea, vomiting, diarrhea
- Asthenia
- Hyperlipidemia, especially hypertriglyceridemia
- Elevated transaminases
- Hyperglycemia
- Fat maldistibution
- Possible increased bleeding in patients with hemophilia
- PR interval prolongation
- QT interval prolongation and torsade de pointes

Special Instructions

- LPV/r tablets can be administered without regard to food, but recognize that administration with or after meals may enhance GI tolerability.
- LPV/r tablets must be swallowed whole. Do not crush or split tablets.
- LPV/r oral solution should be administered with food. A high fat meal increases absorption, especially of the liquid preparation, which may enhance effectiveness by increasing drug exposure.
- If coadministered with didanosine (ddI), ddI should be given 1 hour before or 2 hours after LPV/r.
- LPV/r oral solution can be kept at room temperature up to 77ºF (25ºC) if used within 2 months. If kept refrigerated (2º to 8ºC or 36º to 46ºF) LPV/r oral solution remains stable until the expiration date printed on the label.
- LPV resistance-associated substitutions: LPV/r can be administered once daily (800 mg/200 mg) in adults with fewer than 3 LPV resistance-associated substitutions. Once-daily administration of LPV/r is not recommended for adult patients with 3 or more of the following LPV resistance-associated substitutions: L10F/I/R/V, K20M/N/R, L24I, L33F, M36I, I47V, G48V, I54L/T/V, V82A/C/F/S/T, and I84V.

Metabolism

- CYP 3A4 inhibitor and substrate.
- Dosing of LPV/r in patients with hepatic impairment: LPV/r is primarily metabolized by the liver. Caution should be used when administering LPV to patients with hepatic impairment. No dosing information is

body surface area <0.6 m^2 or those who are unable to reliably swallow a tablet; dosing should be calculated based on body surface area or weight as above.

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs

Pediatric dose (>6 months to 18 years):
For individuals receiving concomitant NVP, EFV, FPV, or NFV. (These drugs induce LPV metabolism and reduce LPV plasma levels; increased LPV/r dosing is required with concomitant administration of these drugs and/or in treatment-experienced patients in whom reduced susceptibility to LPV is suspected [such as those with prior treatment with other PIs].)

Once-daily dosing is **not** recommended.

Body surface area dosing:
300 mg/75 mg LPV/r/m^2 of body surface area per dose twice daily

Weight-based dosing:
<15 kg: 13 mg /3.25 mg LPV/r per kg body weight per dose twice daily

≥15 kg to 45 kg: 11 mg/2.75 mg LPV/r per kg body weight per dose twice daily

≥45 kg: Use adult dose twice daily.

Dosing for 100 mg/25 mg LPV/r Pediatric Tablets for Children **With** Concomitant EFV, NVP, FPV , or NFV		
Body Weight (kg)	Body Surface Area (meter^2)*	Recommended Number of 100 mg/25 mg LPV/r Tablets Given Twice Daily
15 to 20 kg	≥0.6 to <0.8 m^2	2
>20 to 30 kg	≥0.8 to <1.2 m^2	3
>30 to 45 kg	≥1.2 to <1.7 m^2	4 (or two 200 mg/50 mg LPV/r tablets)
>45 kg	≥1.7 m^2	4 or 6 (or two or three 200 mg/50 mg LPV/r adult tablets)**

*Oral solution is available for children age 6 months to 18 years with a body surface area <0.6 m^2 or those who are unable to reliably swallow a tablet; dosing should be calculated based on body surface area or weight as above.
**The higher dose may be considered in treatment-experienced patients where decreased sensitivity to LPV is suspected due to clinical history or documented by resistance testing.

Use of 230 mg/57.5 mg LPV/r per m2 of body surface area (when not coadministered with NVP, EFV, FPV, or NFV) or use of 300 mg/75 mg LPV/r per m2 of body surface area in children (when coadministered with NVP, EFV, FPV, or NFV) is associated with AUC LPV levels similar to AUC achieved with standard doses in adults, but it is associated with lower trough levels in children than in adults. Therefore, some clinicians may choose to initiate therapy with higher doses of LPV/r when coadministered with these drugs or in PI-experienced pediatric patients who may have reduced PI currently available for children or adults with hepatic insufficiency.

- In the coformulation of LPV/r, the RTV acts as a pharmacokinetic enhancer, not as an antiretroviral agent. It does this by inhibiting the metabolism of LPV and increasing LPV plasma concentrations.

susceptibility (see discussion). **Adult (>18 years) dose**: *In patients with fewer than 3* LPV*-associated mutations (see Special Instructions for list):* 800 mg/200 mg LPV/r once daily; **or** 400 mg/100 mg LPV/r twice daily. Do **not** use once-daily dosing in children or adolescents. Once-daily dosing should not be used in patients receiving concomitant therapy with EFV, NVP, FPV, or NFV. *In patients with 3 or more LPV-associated mutations(see Special Instructions for list):* 400 mg/100 mg LPV/r twice daily *In patients receiving concomitant NVP, EFV, FPV, or NFV):* FDA-approved dose is 500 mg/125 mg LPV/r twice daily, given as a combination of 2 tablets of 200/50 mg LPV/r and 1 tablet of 100 mg/25 mg LPV/r. Most Panel members would use 600 mg/150 mg LPV/r for ease of dosing. Once-daily dosing should **not** be used. *LPV/r in combination with saquinavir (SQV) hard gel capsules (Invirase) or in combination with maraviroc (MVC):* SQV and MVC doses may need modification. See sections on **SQV** or **MVC**.	

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents.***)***:***

- *Metabolism*: Cytochrome P450 3A4 (CYP3A4) is the major enzyme responsible for metabolism. There is potential for multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions. Fluticasone, a commonly used inhaled steroid, should not be used in patients treated with lopinavir/ritonavir.

Major Toxicities:

- *More common:* Diarrhea, headache, asthenia, nausea and vomiting, and rash in patients receiving lopinavir/ritonavir with other antiretroviral drugs; hyperlipidemia, especially hypertriglyceridemia.
- *Less common (more severe):* Lipodystrophy.
- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, hemolytic anemia, spontaneous bleeding in hemophiliacs, pancreatitis, elevation in serum transaminases, and hepatitis (life threatening in rare cases). Possible increased bleeding episodes in patients with hemophilia. PR interval prolongation. QT interval prolongation and torsade de pointes may occur. Lopinavir/ritonavir should not be used in the immediate postnatal period in premature infants because life-threatening bradyarrhthymias and cardiac dysfunction have been described with its use in such infants *[1-2]*.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/LPV.html**).

Pediatric Experience:

Lopinavir/ritonavir has been studied in HIV-infected children in combination with NRTIs and NNRTIs *[3-16]*. Ritonavir acts as a pharmacokinetic enhancer by inhibiting the metabolism of lopinavir and therefore increasing the plasma concentration of lopinavir.

Abbott Laboratories Study M98-940 was a Phase I/II open label study that evaluated the pharmacokinetics, tolerability, safety, and efficacy of lopinavir/ritonavir oral solution and either 2 NRTIs or nevirapine plus up to 2 NRTIs in 100 pediatric patients. Through 48 weeks of therapy, the proportion of patients with HIV RNA <400 copies/mL was 37 of 44 (84%) for antiretroviral-

naïve patients and 42 of 56 (75%) for antiretroviral-experienced patients. The mean increase from baseline in CD4 cell count was 404 cells/mm^3 for antiretroviral-naïve and 284 cells/mm^3 for antiretroviral-experienced patients. In patients with HIV RNA >400 copies/mL at 24 or 48 weeks, there were no detectable changes in susceptibility to lopinavir compared with baseline isolates, although there were resistance mutations to NRTIs and NNRTIs in the rebound isolates *[17]*.

There is some controversy about the dosing of lopinavir/ritonavir in children. Children have lower drug exposure than adults when treated with doses that are directly scaled for body surface area. The "directly scaled" dose approximation of the adult dose in children is calculated by dividing the adult dose by the usual adult body surface area of 1.73 m^2. For the adult dose of 400/100 mg lopinavir/ritonavir, the appropriate pediatric dose would be approximately 230/57.5 mg lopinavir/ritonavir per $meter^2$. However, younger children have enhanced lopinavir clearance and need higher drug doses to achieve drug exposures similar to those in adults treated with standard doses. To achieve similar C_{trough} to that observed in adults, the pediatric dose needs to be increased 30% over the directly body surface area-scaled dose.

For 12 children age 6 months to 12 years receiving 230 mg/57.5 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily (without nevirapine), the mean C_{trough} was 4.74 ± 2.93 mcg/mL (about 67% of the adult value of 7.1 ± 2.9 mcg/mL) *[4]*. For 15 children age 6 months to 12 years treated with 300 mg/75 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily (without nevirapine), the mean C_{trough} was 7.91 ± 4.52 mcg/mL, similar to that in adults treated with 400 mg/100 mg lopinavir/ritonavir twice daily *[4]*. Therefore, some clinicians may choose to initiate therapy in children age 6 months to 12 years using 300 mg/75 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily (when given without nevirapine, efavirenz, fosamprenavir, or nelfinavir) rather than the drug-label recommended 230 mg/57.5 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily *[12]*.

The pharmacokinetics of the oral solution at approximately 300 mg/75 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily was evaluated in infants younger than 6 weeks of age *[18]* and infants 6 weeks to 6 months of age *[14]*. Pharmacokinetic values found in these studies are compared to those in older children *[4]* and adults *[17]* in the table below. Values are means; all data shown performed in the absence of NNRTIs.

	Adults *[17]*	**Children** *[4]*	**Children** *[4]*	**Infants 6 wk–6 mo** *[14]*	**Infants <6 weeks** *[18]*
N	19	12	15	18	9
Dose LPV	400 mg	230 mg/m^2	300 mg/m^2	300 mg/m^2	300 mg/m^2
AUC mcg*hr/ml	92.6	72.6	116	74.5	43.4
C_{max} mcg/ml	9.8	8.2	12.5	9.4	5.2
C_{trough} mcg/ml	7.1	4.7	7.9	2.7	2.5
C_{min} mcg/ml	5.5	3.4	6.5	2.0	1.4

Even at this higher dose, predose (C_{trough}) levels were lower in infants than in children >6 months of age and were lower in the youngest infants at age <6 weeks compared with those between 6 weeks and 6 months. Predose (C_{trough}) levels were highly variable, and lower values (median 1.37 mcg/mL; range 0.13–5.98) were found in infants without viral suppression at 16 weeks compared with the higher predose (C_{trough}) values (median 2.28 mcg/mL; range 0.49–8.01) found in those infants with virologic suppression at 16 weeks (N = 17; p = 0.37) *[14]*. Because infants gain weight rapidly in the first months of life, one important way to optimize lopinavir dosing is to weigh the patient and adjust the dose for growth at frequent intervals. Some practitioners anticipate rapid infant growth and prescribe doses somewhat higher than the 300 mg/m^2 body surface area dose to let the infant "grow into" the 300 mg/m^2 body surface area amount.

For children, as in adults, the lopinavir C_{trough} is further reduced by concurrent treatment with NNRTIs or concomitant fosamprenavir or nelfinavir and, as in adults, higher doses of lopinavir are recommended if the drug is given in combination with nevirapine, efavirenz, fosamprenavir, or nelfinavir. In 14 children treated with 230 mg/57.5 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily plus nevirapine, the mean lopinavir C_{trough} was 3.77 ± 3.57 mcg/mL *[4]*. For 12 children treated with 300 mg/75 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily, the mean C_{trough} was 5.62 ± 3.32 mcg/mL. Not only are these trough plasma concentrations lower than those found in adults treated with standard doses of lopinavir/ritonavir, but the variability in concentration is much higher in children than adults *[4, 12]*. In a study of 15 children with HIV infection treated with the combination of lopinavir/ritonavir using an increased dose of 300 mg/75 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily plus efavirenz 14 mg/kg body weight per dose once daily, the median 12-hour lopinavir trough was 5.7 mcg/mL, but there was 34-fold interindividual variation in lopinavir trough concentrations, and 5 of 15 (33%) children had lopinavir 12-hour trough concentrations <1.0 mcg/mL, the plasma concentration needed to inhibit wild-type HIV *[5]*. A pharmacokinetic study in 20 children 10 to 16 years of age treated with the combination of lopinavir/ritonavir 300 mg/75

mg per m^2 of body surface area twice daily plus efavirenz 350 mg/m^2 of body surface area once daily showed adequacy of the lopinavir trough values *[19]*.

Lopinavir/ritonavir 800 mg/200 mg once daily is FDA approved for treatment of HIV infection in therapy-naïve adults >18 years of age. However, once-daily administration cannot be recommended for use in children in the absence of therapeutic drug monitoring because of high interindividual variability in drug exposure and trough plasma concentrations below the therapeutic range for wild-type virus in 21/59 (35.6%) of patients *[20-23]*.
Lopinavir/ritonavir has been shown to be effective as salvage therapy in children with HIV and severe immune suppression *[7, 24]*, although patients with greater prior exposure to antiretrovirals may have slower reductions in virus load to undetectable concentrations *[10, 24]* and less robust response in CD4 percentage *[25]*. Twice-daily doses of lopinavir used in this cohort were 230–300 mg/m^2 of body surface area in 39% of patients, 300–400 mg/m^2 of body surface area in 35%, and >400 mg/m^2 of body surface area per dose in 4% *[25]*.

More important than viral resistance to lopinavir is the relationship of the drug exposure (trough plasma concentration measured just prior to a dose, or C_{trough}) to the susceptibility of the HIV-1 isolate (EC_{50}). The ratio of C_{trough} to EC_{50} is called the inhibitory quotient, and in both adults and children treated with lopinavir/ritonavir, virus load reduction is more closely associated with inhibitory quotient than with either the C_{trough} or EC_{50} alone *[3, 26-28]*. A study of the practical application of the inhibitory quotient to guide therapy using higher doses of lopinavir/ritonavir in children and adolescents showed the safety and tolerability of doses of 400 mg/100 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily (without nevirapine or efavirenz) and 480 mg/120 mg lopinavir/ritonavir per m^2 of body surface area per dose twice daily (with nevirapine or efavirenz) *[16]*. A modeling study suggests the potential utility of therapeutic drug monitoring in children previously treated with protease inhibitors and now on salvage therapy with lopinavir/ritonavir *[29]*.

Nelfinavir (NFV, Viracept)

For additional information see: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Powder for oral suspension: 50 mg/1 level gram scoopful (200 mg/1 level teaspoon)
(Oral powder contains 11.2 mg phenylalanine per gram of powder.)
Tablets: 250 mg and 625 mg

Dosing Recommendations

Neonatal/Infant dose:
Not approved for use in neonates/infants.

Pediatric dose (2–13 years):
45–55 mg/kg twice daily **or** 25–35 mg/kg three times daily

Adolescent/Adult dose:
1,250 mg (five 250-mg tablets or two 625-mg tablets) twice daily **or** 750 mg (three 250-mg tablets) three times daily

(Some adolescents require higher doses than adults to achieve equivalent drug exposures. Consider using therapeutic drug monitoring to guide appropriate dosing.)

Selected Adverse Events

- Diarrhea
- Hyperlipidemia
- Hyperglycemia
- Fat maldistribution
- Possible increase in bleeding episodes in patients with hemophilia
- Serum transaminase elevations

Special Instructions

- Administer with meal or light snack.
- If coadministered with didanosine (ddI), administer NFV 2 hours before or 1 hour after ddI.
- Powder for oral suspension may be mixed with water, milk, pudding, ice cream, or formula; mixture is stable for up to 6 hours.
- Do not mix with any acidic food or juice because of resulting poor taste.
- Do not add water to bottles of oral powder; a special scoop is provided with oral powder for measuring purposes.
- Patients unable to swallow the tablets can dissolve the tablets in a small amount of water. Once dissolved, patients should mix the cloudy mixture well and consume it immediately. The glass should be rinsed with water and the rinse swallowed to ensure that the entire dose is consumed. Tablets can also be crushed and administered with pudding.

Metabolism

- CYP2C19 and 3A4 substrate.
- Metabolized to active M8 metabolite.
- CYP3A inhibitor.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism:* Nelfinavir is metabolized in part by CYP3A4 and is a substrate for CYP2C19 and 3A4. However, ritonavir boosting does not significantly increase nelfinavir concentrations and coadministration is not recommended.
- There is potential for multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Diarrhea (most common). Asthenia, abdominal pain, rash, and lipid abnormalities.
- *Less common (more severe):* Exacerbation of chronic liver disease, fat redistribution.
- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, and elevations in transaminases.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/NFV.html**).

Pediatric Experience: Nelfinavir has been extensively studied in HIV-infected children in combination with other antiretroviral drugs *[1-23]*. In children 2–13 years of age receiving nelfinavir as part of triple antiretroviral therapy in randomized trials, the

proportion of patients with HIV RNA <400 copies/mL through 48 weeks of therapy has been quite variable, ranging from 26% to 69%. Virologic and immunologic response to nelfinavir-based therapy has varied by prior antiretroviral treatment, the number of drugs included in the combination regimen, patient age, and dose used in the study.

Highly variable drug exposure remains a significant problem with the use of nelfinavir in pediatric patients. Unpredictable drug exposure may be exacerbated in pediatric patients because of increased clearance compared with adults and difficulties with adherence to adequate food intake with dosing. In earlier studies, lower doses were used (20–30 mg/kg body weight per dose three times daily) than are currently recommended (45–55 mg/kg body weight per dose twice daily), accounting for some of the lower response rates. The relatively poor ability of nelfinavir to control plasma viremia in infants and children may be related in part to its reduced potency compared with other PIs or NNRTIs, as shown by studies in adults and adolescents *[23-24]*.

Poor outcome with nelfinavir in children may be related in part to lack of palatability of the powder formulation and pharmacokinetic differences in infants, children, and adolescents compared with adults *[6]*. The consistency of food or formula is altered by the addition of pediatric nelfinavir powder, making the drug/admixture unpalatable to some children. These children may prefer the bitterness of the crushed tablets to the sandy consistency of food or formula containing nelfinavir powder. In the PENTA-7 trial, 7 of 20 (35%) infants who started therapy with the nelfinavir powder were switched to crushed tablets because of the difficulty of administering the powder to infants *[1]*.

Analysis of data from PACTG 377 and PACTG 366 showed that CYP2C19 genotypes altered nelfinavir pharmacokinetics and the virologic responses to combination therapy in HIV-1-infected children. These findings suggest that CYP2C19 genotypes are important determinants of nelfinavir pharmacokinetics and virologic response in HIV-1-infected children *[25]*.

Better control of plasma viremia has been observed in antiretroviral-naïve than antiretroviral-experienced children receiving nelfinavir *[8, 11, 16]*. In treatment-experienced patients, better response rates have been seen with 4-drug regimens that have included 2 NRTIs plus an NNRTI *[11, 21]*. When lopinavir/ritonavir was compared with nelfinavir for salvage therapy in 35 treatment-experienced patients after 18 months, 50% of children receiving lopinavir/ritonavir had HIV RNA concentrations <400 copies/mL, compared with <20% of children receiving nelfinavir *[18]*.

Antiviral response in children <2 years of age is significantly less than in older children *[16, 19, 26]*. Improved virologic responses may be seen with nelfinavir-based therapy when it is used as part of a four-drug regimen in children <2 years of age *[14]*. Infants have even lower drug exposures and higher variability in plasma concentrations than children <25 kg; the presence of lower peak drug concentrations and higher apparent oral clearance suggests that both poor absorption and more rapid metabolism may be contributing factors *[3, 15]*. Even with doses of 150 mg/kg/day (given 2–3 times daily), 16.7% of children had peak concentrations and 27.8% of children had 24-hour AUC that were below the 10th percentile of adult values *[13]*. Although it is suggested that dosing in infants might improve if a mg/m^2 of body surface area dosing regimen were used *[2-3]*, such dosing is not recommended at this time. A population pharmacokinetic study predicts three-times daily dosing may be superior to twice-daily dosing in infants <2 months of age *[27]*. This model requires confirmation in infants.

Determining an appropriate and effective dose of nelfinavir in children is complicated by highly variable drug pharmacokinetics. In children 2–12 years of age, administration of a nelfinavir 30 mg/kg/dose three times daily achieves lower drug exposure than administration of a 55 mg/kg/dose twice daily, and this difference is most marked in children weighing <25 kg *[20]*. Children <25 kg may have less than half the drug exposure than children >25 kg when comparable body weight-adjusted doses are used *[7]*. The variability of drug exposure at any given dose is much higher for children than adults *[9]*, which has been attributed at least in part to differences in the diet between children and adults. Two population pharmacokinetic studies of nelfinavir and its active metabolite, M8, describe the large intersubject variability observed in children *[27-28]*.

Studies in adults and children have demonstrated an increased risk of virologic failure associated with low nelfinavir drug exposure, particularly with a nelfinavir C_{min} <1.0 mcg/mL *[29-31]*. In a study of 32 children treated with nelfinavir 90 mg/kg/day divided into 2 or 3 doses a day, 80% of those with morning trough nelfinavir plasma concentration >0.8 mcg/mL had Week 48 HIV RNA concentrations <50 copies/mL, compared with only 29% of those with morning trough <0.8 mcg/mL *[32]*. It is of note that the median age of the group with C_{trough} <0.8 mcg/mL was 3.8 years, while the median age of the group with C_{trough} >0.8 mcg/mL was 8.3 years *[32]*. Therapeutic drug monitoring of nelfinavir plasma concentrations, with appropriate adjustments for low drug exposure, results in improved outcome in adults treated with nelfinavir *[29, 33]*. Given the higher variability of nelfinavir plasma concentrations in infants and children, the benefits of therapeutic drug monitoring and appropriate dose adjustment might be even greater for children. A response rate of 78% was found in a recent pediatric study in which concentrations of nelfinavir and M8 were reported to treating physicians, suggesting a benefit of pharmacokinetic

monitoring in children *[28]*. In PACTG 382, among 50 children 3–16 years of age receiving both efavirenz and nelfinavir, better virologic outcomes (HIV RNA <400 copies/mL) occurred in those patients when nelfinavir AUC_{8h} was greater than the first quartile (>10 mg*h/L) when compared with those below the first quartile: 89% versus 42%, respectively *[5]*. Better virologic responses were obtained when doses were adjusted to achieve target AUC values, an approach that requires therapeutic drug monitoring.

Ritonavir (RTV, Norvir)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/**

Formulations

Oral solution (contains 43% alcohol by volume): 80 mg/mL
Capsules: 100 mg
Tablets: 100 mg

Dosing Recommendations

RTV as a pharmacokinetic enhancer:
The major use of RTV is as a pharmacokinetic enhancer of other PIs. The dose of RTV recommended varies with the different PIs. See dosing information for specific PIs.

In the unusual situation when RTV is prescribed as sole PI:
See manufacturer guidelines.

Selected Adverse Events

- GI intolerance, nausea, vomiting, diarrhea
- Paresthesias—circumoral and extremities
- Hyperlipidemia, especially hypertriglyceridemia
- Hepatitis
- Asthenia
- Taste perversion
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

Special Instructions

- Administer with food to increase absorption and help decrease gastrointestinal side effects.
- If RTV is prescribed with didanosine (ddI), administer drugs 2 hours apart.
- Refrigerate capsules only if the capsules will not be used within 30 days or cannot be stored below 77° F (25° C). Tablets are heat stable.
- Store oral solution at room temperature 68–77°F (20–25°C). Do not refrigerate. Shake well before use.
- Oral solution has limited shelf life; use within 6 months.

To increase tolerance of oral solution in children, try the following:

- Mix solution with milk, chocolate milk, or vanilla or chocolate pudding or ice cream.
- Before administration, give the child ice chips, popsicles, or spoonfuls of partially frozen orange or grape juice concentrate to dull the taste buds or peanut butter to coat the mouth.
- After administration, give the child strong-tasting foods such as maple syrup, cheese, or highly flavored chewing gum.

Metabolism

- CYP3A4 and CYP 2D6 inhibitor; CYP3A4 and CYP1A2 inducer.
- Dosing of RTV in patients with hepatic impairment: RTV is primarily metabolized by the liver. No dosage adjustment is necessary in patients with mild or moderate hepatic impairment. There are no data for dosing adult or pediatric patients with severe hepatic impairment. Use caution when administering RTV to patients with moderate-to-severe hepatic impairment.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism*: Ritonavir is extensively metabolized by and is one of the most potent inhibitors of hepatic cytochrome P450 3A (CYP3A). There is potential for multiple drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions and overlapping toxicities.
- Avoid concomitant use of intranasal/inhaled fluticasone.

Resistance: When ritonavir is used as a pharmacokinetic enhancer, resistance to ritonavir is not clinically relevant.

Major Toxicities:

- *More common:* Nausea, vomiting, diarrhea, headache, abdominal pain, anorexia, circumoral paresthesias, lipid abnormalities.
- *Less common (more severe):* Exacerbation of chronic liver disease, fat maldistribution.
- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, pancreatitis, and hepatitis (life-threatening in rare cases). Allergic reactions, including bronchospasm, urticaria, and angioedema.

Pediatric Experience: Ritonavir is typically used as a pharmacokinetic enhancer of other PIs in children. Ritonavir acts by inhibiting the metabolism of the other PI, therefore increasing the plasma concentration of the second PI. Lopinavir/ritonavir, a PI coformulation, has been well studied in children and is the preferred PI for initial therapy in children (see **Lopinavir/Ritonavir**). Pediatric dosing regimens including boosted fosamprenavir, tipranavir, darunavir, and atazanavir are now available (see individual PIs for more specific information).

Although ritonavir has been well studied, its use in children as a sole PI for initial therapy is recommended only under certain rare circumstances. Ritonavir is associated with a higher incidence of gastrointestinal toxicity and has a greater potential for drug-drug interactions than other PIs. Additionally, poor palatability of the liquid preparation and large pill burden with the capsules (adult dose is six capsules twice daily) limit its use as a sole PI. Concentrations are highly variable in children younger than 2 years of age, and doses of 350–450 mg/m^2 twice a day may not be sufficient for long-term suppression of viral replication in this age group *[1-12]*.

Full-dose ritonavir has been shown to prolong the PR interval in a study of healthy adults who were given ritonavir at 400 mg twice daily *[13]*. There have been reports of potentially life threatening arrhythmias in premature newborn infants treated with lopinavir/ritonavir and thus it should not be used in this group of patients *[14-15]*. The impact on the PR interval of coadministration of ritonavir with other drugs that prolong the PR interval (e.g., macrolides, quinolones, methadone) is not known, and coadministration should be undertaken with caution. In addition, patients with underlying structural heart disease, conduction system abnormalities, ischemic heart disease, or cardiomyopathy may be at increased risk of developing cardiac conduction abnormalities, and ritonavir should be used with caution in these patients.

Saquinavir (SQV, Invirase)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Hard gel capsules (HGC): 200 mg
Film-coated tablets: 500 mg

Dosing Recommendations

Neonate/Infant dose:
Not approved for use in neonates/infants.

Pediatric dose:
Not approved for use in children.

Investigational doses in treatment-experienced children:
SQV must be boosted with ritonavir (RTV):

<2 years of age:
Not recommended—no dose has been determined.

≥2 years of age (conditional recommendation based on limited data):

Weight (kg)	Dose SQV + RTV
5– <15 kg	SQV 50mg/kg + RTV 3 mg/kg, both twice daily
15–40 kg	SQV 50mg/kg + RTV 2.5 mg/kg, both twice daily
≥40 kg	SQV 50mg/kg + RTV 100 mg, both twice daily

Dosing Recommendations for Coadministration with Other Antiretroviral Drugs

SQV in combination with lopinavir/ritonavir (LPV/r)
Pediatric (≥7 years) dose:
SQV 750 mg/m^2 (max 1,600 mg) + LPV/r 400/100 mg/m^2, both twice daily

or

SQV 50 mg/kg + LPV/r 230/57.5 mg/m^2, both twice daily

There are limited or no data on SQV + LPV/r dosing for children <7 years of age. See pediatric experience section for details.

Adolescent (≥16 years)/Adult dose:
SQV 1,000 mg + RTV 100 mg, both twice daily
Should be taken within 2 hours after a full meal. SQV should **only** be used in combination with RTV or LPV/r (never unboosted).

Selected Adverse Events

- GI intolerance, nausea, and diarrhea
- Headache
- Elevated transaminases
- Hyperlipidemia
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

Special Instructions

- Administer within 2 hours after a full meal to increase absorption.
- Sun exposure can cause photosensitivity reactions; advise patients to use sunscreen or protective clothing.

Metabolism

- Cytochrome P450 CYP3A4 substrate, 90% metabolized in the liver.
- Use with caution in patients with hepatic impairment.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Metabolism:* Saquinavir is metabolized by the cytochrome P450 3A4 (CYP3A4) system in the liver, and there is potential for numerous drug interactions.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Diarrhea, abdominal discomfort, headache, nausea, paresthesias, skin rash, and lipid abnormalities.
- *Less common (more severe):* Exacerbation of chronic liver disease, fat maldistribution.

- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, pancreatitis, and elevation in serum transaminases. The combination of saquinavir and ritonavir could lead to prolonged PR and/or QT intervals with potential for heart block and torsades de pointes.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/SQV.html**).

Pediatric Experience: Saquinavir has been studied with NRTIs and other PIs in HIV-infected children *[1-6]*. Initial studies suggested that saquinavir could not be used without boosting by ritonavir or lopinavir/ritonavir. A pharmacokinetic analysis of 5 children younger than 2 years of age and 13 children between the ages of 2 and 5 years using a dose of 50 mg/kg twice daily with boosting ritonavir revealed that drug exposure was lower in children <2 years whereas drug exposure was adequate in those 2 to 5 years of age *[7]*. For this reason, saquinavir should not be given to children younger than 2 years old until an appropriate dose is identified. In children ≥2 years of age, a dose of 50mg/kg twice daily (maximum dose = 1,000 mg) boosted with ritonavir 3 mg/kg twice daily (patients weighing 5 to <15 kg) or 2.5 mg/kg twice daily (patients weighing 15 to 40 kg) resulted in AUC and C_{trough} values similar to those in older children *[8-9]* and adults. Because there is no pediatric formulation, in one study saquinavir was formulated by breaking open the 200-mg hard gel capsules and mixing capsule contents with sugar syrup, jam, or baby formula. Sorbitol syrup was used for patients with diabetes or glucose intolerance *[7]*.

Both saquinavir/ritonavir and saquinavir/lopinavir/ritonavir regimens are promising in the salvage therapy setting *[1, 3-6, 8-10]*. In a study evaluating the addition of saquinavir (750 mg/m^2 of body surface area every 12 hours, maximum dose 1,600 mg) to a regimen containing lopinavir/ritonavir dosed at 400/100 mg/m^2 twice daily (for patients not concurrently taking an NNRTI) or lopinavir/ritonavir 480/120 mg/m^2 twice daily for patients concurrently administered an NNRTI, 18 subjects (median age 14.2 years, range 7.7–17.6) were enrolled. The addition of saquinavir at these doses was well tolerated and did not appear to alter lopinavir pharmacokinetics. Saquinavir dosing was adjusted in 4 subjects (decreased in 3, increased in 1) *[10]*.

In a study of 50 Thai children, saquinavir/lopinavir/ritonavir was initiated as second-line therapy based on extensive NRTI resistance. In this group, saquinavir was dosed at 50 mg/m^2 and lopinavir/ritonavir was dosed at 230/57.5 mg/m^2, all twice daily. After 96 weeks of treatment, 74% of the children achieved an undetectable plasma RNA load at <50 copies/ml. Therapeutic drug monitoring was used to establish adequate C_{min} values and to aid with alterations in drug dosage based upon toxicity. Most C_{min} values for saquinavir were above the desired trough value of 0.1 mg/l. The average C_{min} throughout 96 weeks for saquinavir was 1.37 mg/l, and when saquinavir doses were adjusted, most were decreased by an average of 21% (8mg/kg). Median total cholesterol and HDL values increased significantly through 96 weeks from 144 to 196 mg/dl and from 44 to 57 mg/dl, respectively *[8-9]*.

Tipranavir (TPV, Aptivus)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Oral solution: 100 mg TPV/ml with 116 IU vitamin E/ml
Capsules: 250 mg

Dosing Recommendations

TPV must be used with ritonavir (RTV) boosting. The RTV boosting dose is higher than that used for other PIs.

Pediatric dose (<2 years):
Not approved for use in children <2 years of age.

Pediatric dose (2–18 years):
Body surface area dosing:
TPV 375 mg/m2 + RTV 150 mg/m2, both twice daily
Maximum dose:
TPV 500 mg + RTV 200 mg, both twice daily

Weight-based dosing:
TPV 14 mg/kg + RTV 6 mg/kg, both twice daily
Maximum dose:
TPV 500 mg + RTV 200 mg, both twice daily

Adult dose:
TPV 500 mg (two 250-mg capsules) + RTV 200 mg, both twice daily

Selected Adverse Events

- Intracranial hemorrhage (rare)
- Skin rash
- Nausea, vomiting, diarrhea
- Hepatotoxicity
- Hyperlipidemia
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

Special Instructions

- TPV can be taken with or without food; however, it is recommended that RTV be taken with food. Therefore, the combination may be better tolerated if taken with a meal or snack.
- The oral solution contains 116 IU of vitamin E per mL, which is significantly higher than the reference daily intake for vitamin E. Patients taking the oral solution should not take any supplemental vitamin E greater than a standard multivitamin.
- TPV contains a sulfonamide component. The potential for cross sensitivity between TPV and other drugs in the sulfonamide class is unknown. TPV should be used with caution in patients with sulfonamide allergy.
- Store oral solution at room temperature (77^{o} F); do not refrigerate or freeze. Oral solution must be used within 60 days after first opening bottle.
- Capsules can be kept at room temperature (up to 77^{o}F or 25^{o}C) if used within 2 months. Refrigerate capsules if longer storage or warmer room temperatures anticipated.
- Use TPV with caution in patients who may be at risk of increased bleeding from trauma, surgery, or other medical conditions or who are receiving medications known to increase the risk of bleeding such as antiplatelet agents, anticoagulants, or high doses of supplemental vitamin E.

Metabolism

- Cytochrome P450 CYP3A4 substrate.
- Renal impairment: No adjustment required.
- Liver impairment: No adjustment required for mild impairment; use contraindicated for moderate-to-severe impairment.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.):

- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.
- Tipranavir should be used with caution in patients who may be at risk of increased bleeding from trauma, surgery, or other medical conditions or who are receiving medications known to increase the risk of bleeding such as antiplatelet agents, anticoagulants, or high doses of supplemental vitamin E.

Major Toxicities:

- *More common:* Diarrhea, nausea, fatigue, headache, rash (more frequent in children than in adults), and vomiting. Laboratory abnormalities are elevated transaminases, cholesterol, and triglycerides.
- *Less common (more severe):* Lipodystrophy. Clinical hepatitis and hepatic decompensation, including some fatalities. Patients with chronic hepatitis B or C coinfection or elevations in transaminases are at increased risk of developing further transaminase elevations or hepatic decompensation (approximately 2.5-fold risk). Epistaxis.
- *Rare:* New onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs. Possible association with increased risk of intracranial hemorrhage.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/TPV.html**).

Pediatric Experience: Tipranavir is approved in children ≥2 years of age; approval was based on a multicenter, pediatric study of the safety, efficacy, and pharmacokinetics of tipranavir/ritonavir in HIV-infected children (PACTG 1051/BI-1182.14). This study enrolled treatment-experienced children (with the exception of 3 treatment-naïve patients) 2–18 years of age (median age 11.7 years) with baseline HIV RNA ≥1,500 copies/mL. Children were randomized to 1 of 2 doses of tipranavir coadministered with ritonavir in 3 age strata: tipranavir/ritonavir 290 mg/115 mg per m^2 body surface area (low dose, 58 patients) or 375 mg/150 mg per m^2 body surface area (high dose, 57 patients) twice daily plus optimized background therapy. All children initially received the oral solution; patients who were ≥12 years of age and received the maximum adult dose of 500 mg tipranavir/200 mg ritonavir twice daily could change to tipranavir capsules. At baseline, greater than 50% of patients were resistant to all commercially available protease inhibitors, and the number of protease resistance mutations increased with age *[1]*. Among the low-dose group (tipranavir/ritonavir 290/115 mg/m^2 body surface area), 40% achieved HIV RNA <400 copies/mL and 35% <50 copies/mL at 48 weeks. Among those receiving the higher dose (tipranavir/ritonavir 375/150 mg/m^2 body surface area), 46% achieved HIV RNA <400 copies/mL and 35% <50 copies/mL at 48 weeks. The proportion of patients with HIV RNA <400 copies/mL tended to be greater in the youngest group of patients (70%), who had less baseline resistance. Tipranavir treatment was associated with a mean increase in CD4 cell count of 100 cells/mm^3 and 59 cells/mm^3 in low- and high-dose groups, respectively. Overall, side effects were similar between treatment groups. Twenty-five percent of children experienced a drug-related serious adverse event, and 9% of patients discontinued study drugs due to adverse events. The most common adverse events were gastrointestinal disturbances. Moderate or severe laboratory toxicity was seen in 11% of children (primarily increase in GGT and CPK). Four patients (all in the low-dose group and three-fourths in the younger age group) developed AIDS-defining illnesses through 48 weeks. A Kaplan-Meier analysis comparing AIDS-defining events in the low-dose versus the high-dose group reached statistical significance ($p = 0.04$). In a multivariate model, 3 variables predicted virologic outcome: greater genotypic inhibitory quotient (GIQ), greater adherence, and baseline viral load <100K copies/mL, in that order. GIQ is a ratio of the median tipranavir trough concentration divided by the number of tipranavir mutations. The GIQ was consistently greater in the high-dose group. Based on these findings and the increased number of AIDS-defining events in the low-dose group, the high-dose regimen has been recommended.

Pharmacokinetics of the liquid formulation at steady state were assessed *[2]*. For children 2 to <12 years of age, tipranavir trough concentrations for pediatric patients receiving tipranavir/ritonavir 290/115 mg/m^2 body surface area were consistent with tipranavir trough concentrations achieved in adults receiving standard tipranavir/ritonavir 500 mg/200 mg dosing. However, children 12 to 18 years of age required a higher dose (375/150 mg/m^2 body surface area, 30% higher than the directly scaled adult dose) to achieve drug exposure similar to that in adults receiving the standard tipranavir/ritonavir dose. Population pharmacokinetic analysis demonstrated that tipranavir clearance can be affected by body weight and that volume of distribution can be affected by age *[2]*. Based on these studies the final dose of tipranavir/ritonavir was chosen as 375/150 mg/m^2 body surface area twice daily.

Vitamin E is an excipient in the oral solution, with a concentration of 116 IU of vitamin E and 100 mg tipranavir per ml of solution. Use of the recommended dose of tipranavir (14 mg per kg body weight) results in a vitamin E dose of 16 IU per kg

body weight per day, significantly higher than the reference daily intake for vitamin E (10 IU) and close to the upper limit of tolerability for children. The resultant high dose of vitamin E may lead to an increase in bleeding episodes, which were seen in 5.75% of children receiving the oral solution and 14.3% of children receiving capsules *[1]*.

ENTRY AND FUSION INHIBITORS

Enfuvirtide (ENF, T-20, Fuzeon)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Lyophilized powder for injection:
108-mg vial of ENF. Reconstitution with 1.1 mL sterile water will deliver 90 mg/mL.

Convenience kit*:*
60 single-use vials of ENF (90 mg strength), 60 vials of sterile water for injection, 60 reconstitution syringes (3 mL), 60 administration syringes (1 mL), alcohol wipes

Dosage Recommendations

Pediatric/Adolescent dose (6–16 years):
Children <6 years:
Not approved for use in children <6 years of age.

Children ≥6 years:
2 mg/kg (maximum dose, 90 mg [1 mL]) twice daily injected subcutaneously into the upper arm, anterior thigh, or abdomen

Adolescent (>16 years)/Adult dose:
90 mg (1 mL) twice daily injected subcutaneously into the upper arm, anterior thigh, or abdomen

Selected Adverse Events

- Local injection site reactions
- Increased bacterial pneumonia (unclear association)
- Hypersensitivity reaction—symptoms may include rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum transaminases. Rechallenge is not recommended.

Special Instructions

- Carefully instruct patient or caregiver in proper technique for drug reconstitution and administration of subcutaneous injections. ENF injection instructions are provided with convenience kits.
- Allow reconstituted vial to stand until the powder goes completely into solution, which could take up to 45 minutes. Do not shake.
- Once reconstituted, inject ENF immediately or keep refrigerated in the original vial until use. Reconstituted ENF must be used within 24 hours.
- Must be given subcutaneously; severity of reactions increased if given intramuscularly.
- Give each injection at a site different from the preceding injection site; do not inject into moles, scar tissue, bruises, or the navel. Both the patient/caregiver and health care provider should carefully monitor for signs and symptoms of local infection or cellulitis.
- To minimize local reactions apply ice or heat after injection or gently massage injection site to better disperse the dose. There are reports of injection-associated neuralgia and parasthesia if alternative delivery systems, such as needle-free injection devices, are used.
- Advise patient/caregiver of the possibility of a hypersensitivity reaction; instruct them to discontinue treatment and seek immediate medical attention if the patient develops signs and symptoms consistent with a hypersensitivity reaction.

Metabolism

- Catabolism to constituent amino acids.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents****.)***:

- There are no known significant drug interactions.

Major Toxicities:

- *More common:* Almost all patients (87%–98%) experience local injection site reactions including pain and discomfort, induration, erythema, nodules and cysts, pruritis, and ecchymosis. Usually mild to moderate in severity but can be more severe. Average duration of local injection site reaction is 3 to 7 days, but was >7 days in 24% of patients.
- *Less common (more severe):* Increased rate of bacterial pneumonia (unclear association) and local site cellulitis (up to 11% in certain subgroups of patients in pediatric studies) *[1]*.
- *Rare:* Hypersensitivity reactions (<1%) including fever, nausea and vomiting, chills, rigors, hypotension, and elevated liver transaminases; immune-mediated reactions including primary immune complex reaction, respiratory distress, glomerulonephritis, and Guillain-Barre syndrome. Patients experiencing hypersensitivity reactions should seek immediate

medical attention. Therapy should not be restarted in patients with signs and symptoms consistent with hypersensitivity reactions.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see **http://hivdb.stanford.edu/pages/GRIP/ENF.html**).

Pediatric Experience: Enfuvirtide has been studied in HIV-infected children in combination with other antiretroviral drugs *[1-5]*. PACTG 1005 initially studied enfuvirtide in 14 HIV-infected children age 4–12 years with incomplete viral suppression (plasma RNA >10,000 copies/ml) while on a stable antiretroviral regimen consisting of 2 NRTIs plus an NNRTI or a PI for ≥16 weeks *[2]*. Part A included a single-dose pharmacokinetic evaluation of enfuvirtide given subcutaneously at 15, 30, or 60 mg/m^2 of body surface area. The dose of enfuvirtide that reliably resulted in the target trough concentration (1,000 ng/mL) was 60 mg/m^2 of body surface area per dose, the approximate "equivalent" of a 90-mg dose delivered subcutaneously to an adult with a body surface area of 1.7 m^2. This led to the recommended pediatric label dose in children age 6–16 years of 2 mg/kg (maximum 90 mg) administered subcutaneously twice daily. In a second pediatric study of 25 children age 5–16 years, the 2 mg/kg dose, with a maximum dose of 90 mg, was found to yield drug concentrations similar to 60 mg/m^2 of body surface area dose and drug exposure was found to be independent of age group, body weight, body surface area, and sexual maturation *[6]*. Further data are needed in children <6 years of age. No metabolic induction or inhibition of enfuvirtide has been observed in PACTG 1005 or subsequent studies, nor was there a statistical relationship, within the utilized dosing schedule, between drug exposure with this agent and virologic benefit *[5]*.

Part B of PACTG 1005 evaluated the safety and antiretroviral activity of chronic twice-daily subcutaneous enfuvirtide administration at 60 mg/m^2 per dose in 14 children. For 7 days, the drug was added to each child's background antiretroviral regimen; at Day 7, the background regimen was optimized and enfuvirtide was continued, and children were followed for up to 96 weeks. Two children elected to discontinue enfuvirtide within 24 weeks (1 due to injection aversion, 1 due to an unrelated surgical procedure), 4 discontinued due to virologic failure (defined as >1 log increase in viral load above baseline), and 2 discontinued due to Grade 3 toxicity (thrombocytopenia, edema). In this cohort, most children had local injection site reactions. Seventy-nine percent of children had >0.7 log reduction in HIV RNA by Day 7. At 24 weeks of treatment, 71% had a >1.0 log reduction, 43% were suppressed to <400 copies/mL, and 21% were suppressed to <50 copies/mL *[4]*. However, only 36% of children maintained virologic suppression (>1.0 log decrease in HIV RNA) at Week 96 *[3]*. Significant improvements in CD4 percentage and height *z* score were observed in children receiving enfuvirtide for 48 and 96 weeks.

T20-310, a Phase I/II study of enfuvirtide (2.0 mg/kg subcutaneously, maximum 90 mg, twice daily) plus an optimized background antiretroviral regimen enrolled 52 treatment-experienced children 3–16 years of age for 48 weeks. Of those completing 48 weeks of therapy (64%), the median decrease in HIV RNA was -1.17 $\log_{10}$ copies/mL (n = 32) and there was a median increase of 106 cells/mm^3 (n = 25). Local skin reactions were common in all age groups (87%). Treatment responses at Week 8 were superior in younger (<11 years of age) children when contrasted with adolescents as measured by plasma HIV RNA change from baseline (-2.85 vs. -0.12 $\log_{10}$ copies/mL) or those maintaining HIV RNA <400 (42% vs. 4%). Median increases in CD4 count were 257 cells/mm^3 in children and 84 cells/mm^3 in adolescents. The observed differential responses between children and adolescents probably reflect unique challenges to adherence with the prescribed regimen *[1]*.

An increased rate of bacterial pneumonia was observed in adults treated with enfuvirtide compared with the control arm in the Phase III clinical trials *[7]*. A recent French cohort study with 1,220 patients receiving enfuvirtide and 9,374 patients on optimized therapy without enfuvirtide failed to find an increased risk of pneumonia *[8]*. Pediatric studies have not been powered to answer this question.

Maraviroc (MVC, Selzentry)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Tablets: 150 mg and 300 mg

Dosing Recommendations

Neonate/Infant dose:
Not approved for use in neonates/infants.

Pediatric dose:
Not approved for use in children <16 years.
No data currently available on dosage for children <16 years.

Adolescent (>16 years)/Adult dose:

When given with potent CYP3A inhibitors (with or without CYP3A inducers) including PIs (except tipranavir/ritonavir [TPV/r])	150 mg twice daily
When given with NRTIs, enfuvirtide (ENF), TPV/r, nevirapine (NVP), raltegravir (RAL), and drugs that are not potent CYP3A inhibitors or inducers	300 mg twice daily
When given with potent CYP3A inducers including efavirenz (EFV) and etravirine (ETR) (without a strong CYP3A inhibitor)	600 mg twice daily

Selected Adverse Events

- Abdominal pain
- Cough
- Dizziness
- Musculoskeletal symptoms
- Fever
- Rash
- Upper respiratory tract infections
- Hepatotoxicity
- Orthostatic hypotension

Special Instructions

- Conduct testing with HIV tropism assay prior to use to exclude the presence of CXCR4-using or mixed/dual tropic HIV.
- Can be given without regard to food.
- Instruct patients on how to recognize symptoms of allergic reactions or hepatitis.
- Use caution when administering MVC to patients with underlying cardiac disease.

Metabolism

- Cytochrome P450 (CYP) 3A4 substrate.
- Use caution when administering MVC to patients with hepatic impairment. Because MVC is metabolized by the liver, concentrations may be increased.
- No dosage recommendation in those with renal impairment, but patients with CrCL <50 mL/min should receive MVC and CYP3A inhibitor only if the potential benefits outweigh the risk.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.)***:***

- *Absorption:* Absorption of maraviroc is somewhat reduced with ingestion of a high fat meal; however, maraviroc can be given with or without food.
- *Metabolism:* Maraviroc is a cytochrome P450 (CYP) 3A4 and p-glycoprotein (Pgp) substrate and requires dosage adjustments when administered with CYP- or Pgp-modulating medications.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Cough, fever, upper respiratory tract infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness.
- *Less common (more severe):* Serious adverse events occurred in less than 2% of maraviroc-treated adult patients and included cardiovascular abnormalities (e.g., angina, heart failure, myocardial infarction), hepatic cirrhosis or failure, cholestatic jaundice, viral meningitis, pneumonia, myositis, osteonecrosis, and rhabdomyolysis.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**). Clinical failure may also represent the outgrowth of CXCR4-using (naturally resistant) HIV variants.

Pediatric Experience: The pharmacokinetics, safety, and efficacy of maraviroc in patients <16 years of age have not been established.

INTEGRASE INHIBITORS

Raltegravir (RAL, Isentress)

For additional information see Drugs@FDA: **http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm**

Formulations

Tablets: 400 mg (poloxamer tablet)

Dosing Recommendations	Selected Adverse Events
Neonate/Infant dose: Not approved for use in neonates/infants. **Pediatric dose:** Not approved for use in children <16 years of age. *Investigational dose in children ≥6 years of age (and >25 kg)*: 400 mg twice daily **Adolescent (≥16)/Adult dose:** 400 mg twice daily	• Nausea, diarrhea • Headache • Fever • CPK elevation **Special Instructions** • Can be given without regard to food. **Metabolism** • UGT1A1-mediated glucuronidation. • No dosage adjustment is necessary for patients with mild-to-moderate hepatic insufficiency. No dosing information is available for patients with severe hepatic impairment. • No dosage adjustment is necessary in patients with renal impairment.

Drug Interactions (See also the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.):

- *Metabolism:* The major mechanism of clearance of raltegravir is mediated through glucuronidation by UGT1A1. Inducers of UGT1A1 such as rifampin and tipranavir may result in reduced plasma concentrations of raltegravir while inhibitors of UGT1A1 such as atazanavir may increase plasma concentrations of raltegravir.
- Before administration, the patient's medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities:

- *More common:* Nausea, headache, dizziness, diarrhea, fatigue, and itching.
- *Less common:* Abdominal pain, vomiting. In patients with chronic active hepatitis B and/or C, worsening of laboratory abnormalities from baseline AST, ALT, or total bilirubin is more likely than in patients not coinfected.
- *Rare:* Creatine phosphokinase elevations (Grade 2–4) have been observed in some patients. Myopathy and rhabdomyolysis have been reported. Use raltegravir with caution in patients receiving medications associated with these toxicities. Anxiety, depression, especially in those with prior history. Rash and Stevens-Johnson syndrome have been reported. Thrombocytopenia.

Resistance: The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see **http://www.iasusa.org/resistance_mutations/index.html**) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/cgi-bin/INIResiNote.cgi).

Pediatric Experience: The pharmacokinetics, safety, and efficacy of raltegravir in patients <16 years of age have not been established. Raltegravir in combination with other antiretrovirals is currently being evaluated in IMPAACT 1066, a Phase I/II study in HIV-infected children. The study objectives include selecting an age-appropriate pediatric dose approximating the exposure (AUC and C_{min}) achieved in adults treated with 400 mg twice daily. The intensive pharmacokinetic evaluations are performed on Day 7–12 after raltegravir is added to a stable antiretroviral backbone. After the pharmacokinetic specimens are obtained the backbone regimen is changed.

Initially, intensive PK evaluations were performed in children 12 to <19 years of age, with raltegravir administered with food because there is no food or fasting requirement with its licensed use in adults *[1]*. However, because the effect of food made comparisons to data obtained in fasting adults difficult, the study was then amended to conduct PK evaluations in the fasted state. This led to selection of a dose of 400 mg twice daily of the approved formulation (poloxamer tablet) in children ≥12 to <19 years of age for longer term evaluation of safety and efficacy *[2]*. Preliminary data from 43 participants in this age group after 24 weeks of treatment with raltegravir plus an optimized background regimen demonstrated that 71% had either a viral

load <400 copies/ml or a 1.0 log decrease in viral load; 53% had a viral load <50 copies/ml; and the median CD4 count increase was 111 cells/mm^3. There were 4 Grade 3 adverse reactions judged possibly related to raltegravir (2 neutropenic episodes, 1 liver enzyme elevation, and 1 behavioral change); no participants discontinued therapy due to toxicity *[3]*.

Children ≥6 to <12 years of age were initially treated at a dose of 8 mg/kg twice daily. Evaluation of the pharmacokinetic data in 10 participants again led to choosing a uniform dose of 400 mg twice daily for those with a weight >25 kg. At 12 and 24 weeks of therapy, 78% and 67% of 14 children in this cohort had a viral load <400 copies/ml *[4]*. No unusual toxicity has been seen so far *[4-5]*.

In addition to the approved adult formulation (poloxamer tablet) two investigational raltegravir preparations are being evaluated in IMPAACT 1066: a chewable ethylcellulose formulation in children >2 to <12 years of age *[6]* and an oral suspension for children <2 years of age.

Introduction (Updated May 24, 2010)

Recommendations regarding HIV screening and treatment of pregnant women and prophylaxis for perinatal HIV transmission have evolved considerably in the United States over the last 25 years, reflecting changes in the epidemic and the science of prevention *[1-2]*. Treatment of HIV disease in general and during pregnancy has progressed with an increasing proportion of women receiving combination antiretroviral therapy or triple antiretroviral drug prophylaxis throughout pregnancy. With the implementation of recommendations for universal prenatal HIV counseling and testing, antiretroviral prophylaxis, scheduled cesarean delivery, and avoidance of breastfeeding, the rate of perinatal HIV transmission has dramatically diminished to less than 2% in the United States and Europe *[3-4]*.

These guidelines update the April 29, 2009, Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1 Infected Women for Maternal Health *and* Interventions to Reduce Perinatal HIV Transmission in the United States. The Department of Health and Human Services (HHS) Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, a working group of the Office of AIDS Research Advisory Council (OARAC), develops these guidelines. The guidelines provide health care providers with information for discussion with HIV-infected pregnant women to enable the patient/provider team to make informed decisions regarding the use of antiretroviral drugs during pregnancy and use of elective cesarean delivery to reduce perinatal HIV transmission. The recommendations in the guidelines are accompanied by discussion of various circumstances that commonly occur in clinical practice and the factors influencing treatment considerations. The Panel recognizes that strategies to prevent perinatal transmission and concepts related to management of HIV disease in pregnant women are rapidly evolving and will consider new evidence and adjust recommendations accordingly. The updated guidelines are available from the AIDS*info* Web site (**http://aidsinfo.nih.gov**).

Health care providers considering the use of antiretroviral agents for HIV-infected women during pregnancy must take into account two separate but related issues:

1. antiretroviral treatment of maternal HIV infection; and
2. antiretroviral chemoprophylaxis to reduce the risk of perinatal HIV transmission.

The benefits of antiretroviral therapy for a pregnant woman must be weighed against the risk of adverse events to the woman, fetus, and newborn. Combination drug regimens are considered the standard of care both for treatment of HIV infection and for prevention of perinatal HIV transmission *[2, 5]*. After counseling and discussion, a pregnant woman's informed choice on whether to take antiretroviral drugs either for her treatment or for prevention of mother-to-child transmission or to follow other medical recommendations intended to reduce perinatal HIV transmission should be respected. Coercive and punitive policies are potentially counterproductive in that they may undermine provider-patient trust and could discourage women from seeking prenatal care and adopting health care behaviors that optimize fetal and neonatal well-being.

The current guidelines have been structured to reflect the management of an individual mother-child pair and are organized into a brief discussion of preconception care followed by principles for management of the woman and her infant during the antepartum, intrapartum, and postpartum periods. Key issues and new information discussed in these guidelines include:

- **Rating Scheme for Guidelines (Table 2).** Recommendations are now rated based on strength of recommendation and quality of evidence.

- **Lessons Learned from Clinical Trials of Antiretroviral Interventions to Reduce Perinatal HIV Transmission and Table 3 (Results of Major Studies on Antiretroviral Prophylaxis to Prevent Mother-to-Child HIV Transmission).** Update on recent international clinical trials, including trials of prevention of postnatal transmission and drug resistance in infants infected despite infant or maternal antiretroviral prophylaxis of postnatal infection. The Panel reaffirms that in the United States, where safe, affordable, and feasible alternatives are available and culturally acceptable, breastfeeding is not recommended for HIV-infected women (including those receiving combination antiretroviral therapy or triple antiretroviral drug prophylaxis).
- **Recommendations for Use of Antiretroviral Drugs during Pregnancy.** New discussion of the categories and the criteria used for recommendations about use of specific drugs or drug regimens in pregnancy.
- **Special Situations.** Additional discussion of options for antiretroviral prophylaxis when an HIV/hepatitis B virus (HBV) coinfected pregnant woman does not require antiretroviral therapy for her own health or treatment for hepatitis B disease.
- **Stopping Antiretroviral Therapy during Pregnancy.** Discussion of stopping non-nucleoside reverse transcriptase inhibitor (NNRTI)-based regimens and strategies to reduce the risk of resistance, including short-term continuation of a dual nucleoside reverse transcriptase inhibitor (NRTI) component or switching to a protease inhibitor (PI) prior to discontinuing therapy.
- **Special Considerations for the Use of Antiretroviral Drugs by HIV-Infected Pregnant Women and their Infants.** Updated information on combination antiretroviral drug use and pregnancy outcome and nevirapine hepatic toxicity in pregnancy.
- **Antiretroviral Drug Resistance and Resistance Testing in Pregnancy.** New information regarding resistance following discontinuation of triple drug prophylaxis after delivery and new information from clinical trials on response to therapy following single-dose nevirapine exposure.
- **Intrapartum Antiretroviral Therapy/Prophylaxis.** New references on use of dual NRTI "tail" to reduce risk of nevirapine resistance.
- **Mode of Delivery.** Reorganization and update of section.
- **Neonatal Postnatal Care.**
  - **Short-Term Antiretroviral Drug Safety and Choice for Neonatal Prophylaxis.** Caution on use of lopinavir-ritonavir (and other boosted PIs) in newborns, particularly preterm infants, due to reports of cardiac toxicity (heart block).
  - **Infant Feeding Practices and the Risk of HIV Transmission.** Discussion of new data on feeding infants premasticated food and risk of HIV transmission.
  - **The National Perinatal HIV Hotline.** Contact information for the National Perinatal HIV Hotline, a free consultation service for clinicians.

These recommendations have been developed for use in the United States. Although perinatal HIV transmission occurs worldwide, alternative strategies may be appropriate in other countries. Policies and practices in other countries regarding the use of antiretroviral drugs for reduction of perinatal HIV transmission may differ from the recommendations in these guidelines and will depend on local considerations, including availability and cost of antiretroviral drugs, access by pregnant women to facilities for safe intravenous infusions during labor, and local recommendations regarding breastfeeding by HIV-infected women.

GUIDELINES DEVELOPMENT PROCESS

Table 1. Outline of the Guidelines Development Process

Page 1 of 2

Topic	Comment
Goal of the guidelines	Provide guidance to HIV care practitioners on the optimal use of antiretroviral agents in pregnant women for treatment of HIV infection and for prevention of mother-to-child transmission (MTCT) of HIV in the United States.
Panel members	The Panel is composed of approximately 30 voting members who have expertise in management of pregnant HIV-infected women (e.g., training in either obstetrics/gynecology or women's health) and interventions to prevent MTCT (e.g., pediatric specialists in HIV infection), as well as community representatives with knowledge of HIV infection in pregnant women and interventions to prevent MTCT. The U.S. government representatives, appointed by their agency, include at least one representative from each of the following HHS agencies: Centers for Disease Control and Prevention (CDC), Food and Drug Administration (FDA), Health Resources and Services Administration (HRSA), and the National Institutes of Health (NIH). Members who do not represent the U.S. government agencies are selected after an open announcement to call for nominations. Each member serves on the Panel for a 3-year period, with an option for reappointment. A list of current Panel members can be found on **Page iv** of this document.
Financial disclosure	All members of the Panel submit a written financial disclosure annually. A list of the latest disclosures can be found in the **Appendix** section of this document.
Users of the guidelines	Providers of care to HIV-infected pregnant women and to HIV-exposed infants
Funding source	Office of AIDS Research, NIH
Evidence collection	The recommendations are generally based on studies published in peer-reviewed journals. On some occasions, particularly when new information may affect patient safety, unpublished data presented at major conferences or prepared by the FDA and/or manufacturers as warnings to the public may be used as evidence to revise the guidelines.
Recommendation grading	See **Table 2**.
Method of synthesizing data	Each section of the guidelines is assigned to a small group of Panel members with expertise in the area of interest. The members synthesize the available data and propose a recommendation to the Panel. All proposals are discussed at monthly teleconferences and then are voted on by the Panel members before being endorsed as official recommendations.

Table 1. Outline of the Guidelines Development Process
Page 2 of 2

Topic	Comment
Other guidelines	These guidelines focus on HIV-infected pregnant women and their infants. Separate guidelines outline the use of antiretroviral therapy in nonpregnant HIV-infected adults and adolescents, HIV-infected children, and those who experience occupational or nonoccupational exposure to HIV. These guidelines are also available at the AIDS*info* Web site (**http://www.aidsinfo.nih.gov**). There is brief discussion of preconception management for nonpregnant women of reproductive age in this document. However, for more detailed discussion on issues of treatment of nonpregnant adults, the Working Group defers to the designated expertise offered by Panels that have developed those guidelines.
Update plan	The Panel meets monthly by teleconference to review data that may warrant modification of the guidelines. Updates may be prompted by new drug approvals (or new indications, dosing formulations, or frequency), new significant safety or efficacy data, or other information that may have a significant impact on the clinical care of patients. For cases in which significant new data become available that may affect patient safety, a warning announcement with the Panel's recommendations may be made on the AIDS*info* Web site until appropriate changes can be made in the guidelines document. Updated guidelines are available at the AIDS*info* Web site (**http://www.aidsinfo.nih.gov**).
Public comments	After release of an update on the AIDS*Info* Web site, the public is given a 2-week period to submit comments to the Panel. These comments are reviewed, and a determination is made as to whether revisions are indicated. The public is also able to submit comments to the Panel at any time at **contactus@aidsinfo.nih.gov**.

Basis for Recommendations

Recommendations in these guidelines are based on scientific evidence and expert opinion. Each recommended statement is rated with a letter of **A**, **B,** or **C** that represents the strength of the recommendation and with a numeral **I**, **II,** or **III**, according to the quality of evidence.

Table 2. Rating Scheme for Recommendations

Strength of Recommendation	Quality of Evidence for Recommendation
A: Strong recommendation for the statement **B:** Moderate recommendation for the statement **C:** Optional recommendation for the statement	**I:** One or more randomized trials with clinical outcomes and/or validated laboratory endpoints **II:** One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes **III:** Expert opinion

Lessons from Clinical Trials of Antiretroviral Interventions to Reduce Perinatal Transmission of HIV (Updated May 24, 2010)

One of the major achievements in HIV research was the demonstration by the Pediatric AIDS Clinical Trials Group 076 (PACTG 076) clinical trial that administration of zidovudine to the pregnant woman and her infant could reduce the risk of perinatal transmission by nearly 70% *[1]*. In PACTG 076, zidovudine was started orally at 14 to 34 weeks gestation, given intravenously to the mother during labor, and administered to the infant for 6 weeks.

Following the results of PACTG 076, in the United States and in other resource-abundant countries, implementation of the zidovudine regimen coupled with increased antenatal HIV counseling and testing rapidly resulted in significant declines in transmission *[2-5]*. Subsequent clinical trials and observational studies demonstrated that combination antiretroviral prophylaxis (initially dual and then triple combination therapy) given to the mother antenatally was associated with further declines in transmission to less than 2% *[2, 6-7]*. It is currently estimated that fewer than 200 HIV-infected infants are now born each year in the United States *[4, 8]*. However, although new perinatal HIV infections are becoming rare in resource-rich countries, infections continue to occur, and the birth of an infected infant is a sentinel event representing missed opportunities and barriers to prevention *[9-10]*. Important obstacles to eradication of perinatal transmission in the United States include the continued increase of HIV infection among women of childbearing age; absent or delayed prenatal care, particularly in women using illicit drugs; acute (primary) infection in late pregnancy and in women who are breastfeeding; poor adherence to prescribed antiretroviral regimens; and lack of full implementation of routine, universal prenatal HIV counseling and testing *[10]*.

Within resource-limited settings, the complexity and cost of the three-part PACTG 076 regimen significantly limit its applicability and implementation. Thus, researchers began to explore the development of shorter, less expensive prophylactic regimens more applicable to resource-constrained settings. Clinical trials initially focused on shortened zidovudine-alone prophylaxis regimens and moved to evaluating whether combination antiretroviral regimens, such as short-course zidovudine combined with lamivudine, might have improved efficacy over zidovudine alone. Studies also evaluated whether even simpler, less expensive, single-drug regimens, such as single-dose intrapartum/neonatal nevirapine, would be effective and whether combining such regimens with other short-course regimens might result in improved efficacy. These studies have provided important insights into the mechanisms of action of antiretroviral drugs in reducing perinatal transmission and in determining optimal regimens for use in the United States and other resource-rich countries, as discussed below.

MECHANISMS OF ACTION OF ANTIRETROVIRAL PROPHYLAXIS IN REDUCING PERINATAL TRANSMISSION OF HIV

Panel's Recommendation:

- ***Antiretroviral drugs reduce perinatal transmission by several mechanisms, including lowering maternal antepartum viral load and pre- and post-exposure prophylaxis of the infant. Therefore, for prevention of perinatal transmission of HIV, combined antepartum, intrapartum, and infant antiretroviral prophylaxis is recommended (AI).***

There are a number of mechanisms through which zidovudine or other antiretroviral drugs can reduce perinatal transmission. One important mechanism is by decreasing maternal viral load in the blood and genital secretions via antenatal drug administration, particularly in women with high viral loads. However, antiretroviral drugs have been shown to reduce the risk of transmission even among women with HIV RNA levels <1,000 copies/mL *[11]*. Additionally, the level of HIV RNA at delivery and receipt of antenatal antiretroviral therapy are each independently associated with the risk of transmission, suggesting that antiretroviral prophylaxis does not work solely through reduction in viral load *[2, 12]*.

An additional mechanism of protection is pre-exposure infant prophylaxis provided by administration of antiretroviral drugs that cross the placenta from the mother to the infant, resulting in adequate systemic drug levels in the infant. This mechanism of protection is likely particularly important during the infant's passage through the birth canal, a time of intensive exposure to maternal genital tract virus. Post-exposure infant prophylaxis is provided through administration of drug to the infant after birth. This mechanism protects the infant from cell-free or cell-associated virus that might have obtained access to the fetal/infant systemic circulation through maternal-fetal transfusion during uterine contractions occurring in labor or through systemic dissemination of virus swallowed by the infant during passage through the birth canal.

It is likely that efficacy of antiretroviral drugs in reducing perinatal transmission is multi-factorial, and each of these mechanisms is contributory. The efficacy of antiretroviral regimens administered only during labor and/or to the newborn in reducing perinatal transmission, as discussed below, demonstrates the importance of the pre- and post-exposure components of prophylaxis in reducing perinatal transmission *[13-19]*.

LESSONS FROM INTERNATIONAL CLINICAL TRIALS OF SHORT-COURSE REGIMENS FOR PREVENTION OF PERINATAL TRANSMISSION OF HIV

Panel's Recommendations:

- ***Combination antepartum antiretroviral drug regimens are more effective than single-drug regimens in reducing perinatal transmission and should be used for maternal prophylaxis (AI).***
- ***Longer duration of antepartum antiretroviral prophylaxis (e.g., starting at 28 weeks gestation) is more effective than shorter duration (e.g., starting at 36 weeks gestation). Therefore, for women who do not require immediate initiation of therapy for their own health, prophylaxis should be started after the first trimester and no later than 28 weeks gestation (see Recommendations for Use of Antiretroviral Drugs during Pregnancy) (AI).***
- ***In the absence of antepartum antiretroviral therapy, intrapartum antiretroviral drugs should be administered in combination with infant antiretroviral prophylaxis to reduce the risk of perinatal transmission (see Intrapartum Care) (AI), although this combination is not as effective as antepartum/intrapartum/infant prophylaxis.***
- ***If women do not receive antepartum or intrapartum antiretroviral drugs, postnatal infant antiretroviral prophylaxis is recommended with 6 weeks of zidovudine (see Neonatal Postnatal Care) (AII).***
- ***In the United States, the addition of single-dose intrapartum/newborn nevirapine to the standard antepartum combination antiretroviral regimens used for prophylaxis or treatment in pregnant women is not recommended because it does not appear to provide additional efficacy in reducing transmission and may be associated with the development of nevirapine resistance (AI).***
- ***Breastfeeding is not recommended for HIV-infected women (including those receiving combination antiretroviral therapy) in the United States, where safe, affordable and feasible alternatives are available and culturally acceptable (AII).***

A number of simple regimens have been identified that are effective in reducing perinatal transmission in resource-limited countries (see **Table 3**). Because the studies involved different patient populations residing in different geographic locations, infected with different viral subtypes and having different infant feeding practices, direct comparison of results between trials is difficult. However, some general conclusions can be drawn from the study results that are relevant to understanding use of antiretroviral drugs in both resource-limited and -rich countries.

Short-term efficacy has been demonstrated for a number of short-course antiretroviral regimens, including those with zidovudine alone; zidovudine plus lamivudine; single-dose nevirapine; and, more recently, combining single-dose nevirapine with either short-course zidovudine or zidovudine/lamivudine *[13-14, 16-23]*. In general, combination regimens are more effective than single-drug regimens in reducing perinatal transmission. Additionally, when it is feasible and affordable, a longer three-part regimen given antenatally, intrapartum, and postpartum is superior in preventing perinatal transmission than a shorter two-part antepartum/intrapartum or intrapartum/postpartum regimen *[14, 24-25]*.

Almost all trials in resource-limited countries have included an oral intrapartum prophylaxis component, with varying durations of maternal antenatal and/or infant (and sometimes maternal) postpartum prophylaxis. Perinatal transmission is reduced by regimens with antenatal components starting as late as 36 weeks gestation and lacking an infant prophylaxis component *[20-22]*. However, longer duration of antenatal therapy (starting at 28 weeks gestation) is more effective than shorter duration (starting at 36 weeks gestation), suggesting that a significant proportion of *in utero* transmission occurs between 28 and 36 weeks gestation *[23]*. More prolonged post-exposure prophylaxis of the infant does not appear to substitute for longer duration of maternal therapy *[23]*.

Because some women may lack antenatal care and first present for care during labor (possibly the majority of pregnant women in some resource-limited settings), regimens that do not include maternal therapy during pregnancy have been evaluated. Regimens that include only intrapartum and postpartum drug administration have also been shown to be effective in reducing perinatal transmission *[13-14, 16]*. However, intrapartum pre-exposure prophylaxis alone with nucleoside reverse transcriptase inhibitor (NRTI) drugs (zidovudine/lamivudine), without continued post-exposure prophylaxis of the infant, is not effective in reducing transmission*[14]*. The SAINT trial demonstrated that the two proven effective intrapartum/postpartum regimens (zidovudine/lamivudine or single-dose intrapartum/newborn nevirapine) are similar in efficacy and safety *[16]*.

In some situations, maternal antepartum and intrapartum therapy may not be possible, and only infant prophylaxis can be provided. Based on epidemiologic data *[15]*, in resource-rich countries, the standard prophylaxis regimen in the absence of maternal therapy is 6 weeks of infant zidovudine. To define the optimal infant prophylaxis regimen in the absence of maternal therapy, an ongoing multi-national study in infants born to women who have not received antenatal therapy is comparing the standard 6-week infant zidovudine regimen to 6 weeks of zidovudine combined with either one or two additional drugs.

In resource-limited settings, administration of even 6 weeks of infant zidovudine may be difficult to achieve, and single-dose nevirapine is widely used. In a study in South Africa of infants born to mothers who did not receive antenatal or intrapartum therapy, administration of single-dose infant nevirapine given within 24 hours of delivery was compared to 6 weeks of infant zidovudine therapy; overall perinatal transmission rates were not significantly different *[19]*. A trial in Malawi compared single-dose infant nevirapine to a combination of single-dose nevirapine with a week of zidovudine therapy when no antenatal maternal therapy was received. The addition of 1 week of zidovudine therapy to infant single-dose nevirapine reduced the risk of transmission by 36% compared to infant single-dose nevirapine alone *[17]*. However, when maternal intrapartum nevirapine was received, thereby providing pre-exposure prophylaxis in addition to post-exposure prophylaxis, single-dose infant nevirapine alone was as effective as the combined nevirapine/zidovudine infant post-exposure prophylaxis regimen *[18]*. One problem with the use of single-dose infant nevirapine alone or in combination with a week of zidovudine to prevent transmission is the risk of nevirapine resistance emerging in infants who become infected despite receiving antiretroviral prophylaxis *[26]*. Thus, in the United States, the standard recommendation for infant prophylaxis in the absence of maternal antenatal and intrapartum therapy remains 6 weeks of infant zidovudine.

In an attempt to improve the efficacy of short-course regimens but retain a regimen cost-appropriate for resource-limited countries, more recently researchers have evaluated whether the addition of a potent intrapartum intervention—the single-dose nevirapine regimen—to short-course regimens might increase efficacy. In the setting of short-course antenatal zidovudine alone or zidovudine/lamivudine, the Perinatal HIV Prevention Trial (PHPT)-2 study in nonbreastfeeding women in Thailand, the DITRAME studies in a partially breastfeeding population in the Cote d'Ivoire, and the Mashi study in Botswana (in the formula-fed, but not the breastfed, strata) demonstrated that the addition of single-dose nevirapine did significantly increase efficacy *[24, 27-28]*. The relative importance of the maternal and infant components of single-dose nevirapine in the context of short-course zidovudine regimens remains unclear. The Thailand PHPT-2 study suggests that the infant nevirapine dose at 48–72 hours of life may not add significant efficacy to the maternal nevirapine dose alone; however, the Botswana Mashi study suggests that maternal nevirapine may not be necessary when infant single-dose nevirapine is provided at birth *[27-28]*.

Whether single-dose nevirapine provides any additional efficacy when combined with the standard recommended antiretroviral prophylaxis regimens used in the United States (e.g., combination antiretroviral drugs in women with HIV RNA >1,000 copies/mL) was evaluated in PACTG 316, a clinical trial conducted in the United States, Europe, Brazil, and the Bahamas. This study

demonstrated that for nonbreastfeeding women in resource-rich countries, the addition of single-dose nevirapine did not offer significant benefit in the setting of combination antiretroviral therapy throughout pregnancy and very low viral load at the time of delivery *[7]*. Thus, the addition of single-dose intrapartum nevirapine is generally not recommended for women in the United States who are receiving the standard recommended antenatal antiretroviral prophylaxis regimens (see **Intrapartum Care** section).

In the United States and other parts of the world where replacement feeding is affordable, feasible, acceptable, sustainable, and safe, breastfeeding by HIV-infected women (including those receiving antiretroviral drugs) is not recommended. A number of studies have evaluated the use of maternal or infant antiretroviral prophylaxis during breastfeeding to reduce postnatal transmission (see **Table 3**). Observational data and randomized clinical trials have demonstrated that infant prophylaxis (primarily using daily infant nevirapine) during breastfeeding significantly decreases the risk of postnatal transmission in breast milk and that maternal triple drug prophylaxis during breastfeeding may likewise decrease postnatal infection *[29-36]*. However, neither infant nor maternal postpartum antiretroviral prophylaxis completely eliminates the risk of HIV transmission through breast milk, and the combination of maternal and infant postpartum regimens has not been evaluated. Therefore, breastfeeding is not recommended for HIV-infected women in the United States (including those receiving combination antiretroviral drug regimens), where safe, affordable and feasible alternatives are available and culturally acceptable. Both infant nevirapine prophylaxis and maternal triple drug prophylaxis during breastfeeding may be associated with the development of antiretroviral drug resistance in infants who become infected despite prophylaxis *[37-40]*. Three studies have found multi-class drug resistance in breastfeeding infants who became infected despite maternal triple drug prophylaxis *[38-40]*.

PERINATAL TRANSMISSION OF HIV AND MATERNAL HIV RNA COPY NUMBER

Panel's Recommendation:

- ***Use of antiretroviral drugs during pregnancy for prevention of perinatal transmission should be discussed with and provided to all infected pregnant women regardless of HIV RNA level (AI).***

Initial data regarding the correlation of viral load with risk of perinatal transmission were conflicting. Some studies suggested an absolute correlation between HIV RNA copy number and risk of transmission *[41]*. However, although higher HIV RNA levels have been observed in women who transmitted HIV to their infants, overlap in HIV RNA copy number has been observed in both women who did and women who did not transmit the virus. Transmission has been observed across the entire range of HIV RNA levels (including in women with undetectable viral load), and the predictive value of HIV RNA copy number for transmission in an individual woman is modest *[42-44]*. In PACTG 076, antenatal maternal HIV RNA copy number was associated with HIV transmission in women receiving placebo. In women receiving zidovudine, the relationship was markedly attenuated and no longer statistically significant *[12]*. An HIV RNA threshold below which there was no risk of transmission was not identified; zidovudine was effective in reducing transmission regardless of maternal HIV RNA copy number *[12, 45]*.

More recent data from larger numbers of zidovudine-treated, HIV-infected pregnant women indicate that HIV RNA levels correlate with risk of transmission even in women treated with antiretroviral agents *[46-49]*. Although the risk of perinatal transmission in women with undetectable HIV RNA levels appears to be extremely low, transmission from mother to infant has been reported among women with all levels of maternal HIV RNA. Additionally, although HIV RNA may be an important risk factor for transmission, other factors also appear to play a role *[46, 49-50]*.

Although there is a general correlation between viral load in plasma and in the genital tract, discordance has also been reported, particularly between HIV proviral load in blood and genital secretions, especially in the presence of other genital tract infections *[51-54]*. If exposure to HIV in the maternal genital tract during delivery is a risk factor for perinatal transmission, plasma HIV RNA levels might not always be an accurate indicator of risk. Long-term changes in one body compartment (such as can occur with antiretroviral treatment) may or may not be associated with comparable changes in other compartments. Further studies are needed to determine the effect of antiretroviral drugs on genital tract viral load and the association of such effects on the risk of perinatal HIV transmission. In the short-course zidovudine trial in Thailand, plasma and cervicovaginal HIV RNA levels were reduced by zidovudine treatment, and each independently correlated with perinatal transmission *[55]*. Use of antiretroviral drugs during pregnancy for prevention of perinatal transmission should be discussed with and offered to all infected pregnant women regardless of their HIV RNA level.

Results of epidemiologic and clinical trials suggest that women receiving potent combinations of antiretroviral drugs that effectively reduce HIV RNA to <1,000 copies/mL or undetectable levels have very low rates of perinatal transmission *[2, 6-7, 56]*. However, because transmission can occur even at low or undetectable HIV RNA copy numbers, HIV RNA levels should not be a determining factor when deciding whether to use antiretroviral drugs for prevention of perinatal transmission. Additionally, the efficacy of antiretroviral drugs is not solely related to lowering viral load *[2, 11-12, 57]*. Therefore, antiretroviral prophylaxis should be given even to women who have a very low or undetectable viral load on no therapy.

Table 3. Results of Major Studies on Antiretroviral Prophylaxis to Prevent Mother-to-Child HIV Transmission

Study Location(s) Mode of Infant Feeding	Antiretroviral Drugs	Antepartum and Intrapartum	Postpartum	Mother-to-Child Transmission Rate and Efficacy
PACTG 076 United States, France *[1]* Formula feeding	ZDV vs placebo	Long (from 14 weeks) Intravenous IP	Long (6 weeks), infant only	• MTCT at 18 months was 8.3% in ZDV arm vs 25.5% in placebo arm (68% efficacy).
CDC short-course ZDV trial Thailand *[22]* Formula feeding	ZDV vs placebo	Short (from 36 weeks) Oral IP	None	• MTCT at 6 months was 9.4% in ZDV arm vs 18.9% in placebo arm (50% efficacy).
DITRAME (ANRS 049a) trial Côte d'Ivoire, Burkina Faso *[21, 58]* Breastfeeding	ZDV vs placebo	Short (from 36 weeks) Oral IP	Short (1 week), mother only	• MTCT was 18.0% in ZDV arm vs 27.5% in placebo arm at 6 months (38% efficacy) and 21.5% vs 30.6% at 15 months (30% efficacy). • MTCT was 22.5% in ZDV arm vs 30.2% in placebo arm in pooled analysis at 24 months (26% efficacy).
CDC short-course ZDV trial Côte d'Ivoire *[20-21]* Breastfeeding	ZDV vs placebo	Short (from 36 weeks) Oral IP	None	• MTCT was 16.5% in ZDV arm vs 26.1% in placebo arm at 3 months (37% efficacy). • MTCT was 22.5% in ZDV arm vs 30.2% in placebo arm in pooled analysis at 24 months (26% efficacy).

PETRA trial South Africa, Tanzania, and Uganda *[14]* Breastfeeding and formula feeding	AP/IP/PP ZDV + 3TC vs IP/PP ZDV + 3TC vs IP-only ZDV + 3TC vs placebo	Short (from 36 weeks) Oral IP	Short (1 week), mother and infant	• MTCT was 5.7% at 6 weeks for AP/IP/PP ZDV + 3TC, 8.9% for IP/PP ZDV + 3TC, 14.2% for IP-only ZDV + 3TC, and 15.3% for placebo (efficacy compared to placebo: 63%, 42%, and 0%, respectively). • MTCT was 14.9% at 18 months for AP/IP/PP ZDV + 3TC, 18.1% for IP/PP ZDV + 3TC, 20.0% for IP-only ZDV + 3TC, and 22.2% for placebo (efficacy compared to placebo: 34%, 18%, and 0%, respectively).
HIVNET 012 trial Uganda *[13]* Breastfeeding	sdNVP vs ZDV	No AP ARV Oral IP: sdNVP vs oral ZDV	sdNVP within 72 hours of birth (infant only) vs ZDV (1 week), infant only	• MTCT was 11.8% in NVP arm vs 20.0% in ZDV arm at 6 to 8 weeks (42% efficacy); 15.7% in NVP arm vs 25.8% in ZDV arm at 18 months (41% efficacy).
SAINT trial South Africa *[16]* Breastfeeding and formula feeding	sdNVP vs ZDV + 3TC	No AP ARV Oral IP: sdNVP vs ZDV + 3TC	sdNVP within 48 hours of birth (mother and infant) vs ZDV + 3TC (1 week), mother and infant	• MTCT was 12.3% in sdNVP arm vs 9.3% in ZDV + 3TC arm at 8 weeks (difference not statistically significant, p=0.11).
Perinatal HIV Prevention Trial (PHPT-1) Thailand *[23]* Formula feeding	Four ZDV regimens with different durations of AP and infant PP administration, no placebo	Long (from 28 weeks), short (from 36 weeks) Oral IP	Long (6 weeks), short (3 days), infant only	• Short-short arm stopped at interim analysis (10.5%). MTCT was 6.5% in long-long arm vs 4.7% in long-short arm and 8.6% in short-long arm at 6 months (no statistical difference). *In utero* transmission was significantly higher with short vs long maternal therapy regimens (5.1% vs 1.6%).
PACTG 316 trial Bahamas, Belgium, Brazil, France, Germany, Italy, Spain, Sweden, Switzerland, United Kingdom, United States *[7]* Formula feeding	sdNVP vs placebo among women already receiving ZDV alone (23%) or ZDV + other ARV drugs (77% combination therapy)	Nonstudy ARV regimen Oral IP: placebo vs sdNVP + intravenous ZDV	Placebo vs sdNVP within 72 hours of birth + nonstudy ARV drugs (ZDV), infant only	• 77% of women received dual or triple combination ARV regimens during pregnancy. • Trial stopped early due to very low MTCT in both arms: 1.4% in sdNVP arm vs 1.6% in placebo arm (53% of MTCT was *in utero*).

Perinatal HIV Prevention Trial (PHPT-2) Thailand *[27]* Formula feeding	ZDV alone vs ZDV + maternal and infant sdNVP vs ZDV + maternal sdNVP	ZDV from 28 weeks Oral IP: ZDV alone or ZDV + sdNVP	ZDV for 1 week with or without sdNVP, infant only	• ZDV-alone arm was stopped due to higher MTCT than the NVP–NVP arm (6.3% vs 1.1%). In arms in which the mother received sdNVP, MTCT rate did not differ significantly between the infant receiving or not receiving sdNVP (2.0% vs 2.8%).
DITRAME Plus (ANRS 1201.0) trial Abidjan, Côte d'Ivoire *[24]* Breastfeeding and formula feeding	Open label, ZDV + sdNVP	ZDV from 36 weeks Oral IP: ZDV plus sdNVP	sdNVP + ZDV for 1 week, infant only	• MTCT was 6.5% (95% CI 3.9%–9.1%) at 6 weeks; MTCT for historical control group receiving short ZDV (98% breastfed) was 12.8%.
DITRAME Plus (ANRS 1201.1) trial Abidjan, Côte d'Ivoire *[24]* Breastfeeding and formula feeding	Open label, ZDV + 3TC + sdNVP	ZDV + 3TC from 32 weeks (stopped at 3 days PP) Oral IP: ZDV + 3TC + sdNVP	sdNVP + ZDV for 1 week, infant only	• MTCT was 4.7% (95% CI 2.4%–7.0%) at 6 weeks; MTCT for historical control group receiving short ZDV (98% breastfed) was 12.8%.
NVAZ trial Malawi *[17]* Breastfeeding	Neonatal sdNVP vs sdNVP + ZDV	No AP or IP ARV (latecomers)	sdNVP with or without ZDV for 1 week, infant only	• MTCT was 15.3% in sdNVP + ZDV arm and 20.9% in sdNVP-only arm at 6 to 8 weeks. MTCT rate at 6 to 8 weeks among infants who were HIV uninfected at birth was 7.7% and 12.1%, respectively (36% efficacy).
Postnatal NVP + ZDV trial Malawi *[18]* Breastfeeding	Neonatal sdNVP vs sdNVP + ZDV	No AP ARV Oral IP: sdNVP	sdNVP with or without ZDV for 1 week, infant only	• MTCT was 16.3% in NVP + ZDV arm and 14.1% in sdNVP-only arm at 6 to 8 weeks (difference not statistically significant). MTCT rate at 6 to 8 weeks among infants who were HIV uninfected at birth was 6.5% and 16.9%, respectively.
Post-exposure Infant Prophylaxis South Africa *[19]* Breastfeeding and formula feeding	Neonatal sdNVP vs ZDV for 6 weeks	No AP or IP ARV	sdNVP vs ZDV for 6 weeks	• For formula-fed infants only, MTCT was 14.3% in sdNVP arm vs14.1% in ZDV arm at 6 weeks (not significant, p=0.30). For breastfed infants only, MTCT was 12.2% in sdNVP arm and 19.6% in ZDV arm (p=0.03).

Mashi Botswana *[28, 59]* Breastfeeding and formula feeding	Initial: short-course ZDV with/without maternal and infant sdNVP and with/without breastfeeding Revised: short-course ZDV + infant sdNVP with/without maternal sdNVP and with/without breastfeeding; women with CD4 <200 receive combination therapy	1st randomization ZDV from 34 weeks Oral IP: ZDV + either sdNVP vs placebo	2nd randomization Breastfeeding + ZDV (infant) 6 months + sd NVP, infant only vs Formula feeding + ZDV (infant) 4 weeks + sdNVP, infant only	• Initial design: In formula-feeding arm, MTCT at 1 month was 2.4% in maternal and infant sdNVP arm and 8.3% in placebo arm (p=0.05). In breastfeeding + infant ZDV arm, MTCT at 1 month was 8.4% in sdNVP arm and 4.1% in placebo arm (difference not statistically significant). • Revised design: MTCT at 1 month was 4.3% in maternal + infant sdNVP arm and 3.7% in maternal placebo + infant sdNVP arm (no significant difference; no interaction with mode of infant feeding). • MTCT at 7 months was 9.1% in breastfeeding + ZDV arm and 5.6% in formula feeding arm; mortality at 7 months was 4.9% in breastfeeding + ZDV arm vs 9.3% in formula feeding arm; HIV-free survival at 18 months was 15.6% breastfeeding + ZDV arm vs 14.2% formula feeding arm.
SWEN Uganda, Ethiopia, India *[30]* Breastfeeding	sdNVP vs NVP for 6 weeks	No AP ARV Oral IP: sdNVP	Infant sdNVP vs NVP for 6 weeks	• Postnatal infection in infants uninfected at birth: - MTCT at 6 weeks was 5.3% in sdNVP arm vs 2.5% in extended NVP arm (risk ratio 0.54, p=0.009). - MTCT at 6 months was 9.0% in sdNVP arm vs 6.9% in extended NVP arm (risk ratio 0.80, p=0.16). • HIV-free survival significantly lower in extended NVP arm at both 6 weeks and 6 months

PEPI-Malawi Trial Malawi *[29]* Breastfeeding	sdNVP + ZDV for 1 week (control) vs two extended infant regimens (NVP or NVP/ZDV) for 14 weeks	No AP ARV Oral IP: sdNVP (if mother presents in time)	Infant sdNVP + ZDV for 1 week (control) vs control + NVP for 14 weeks vs control + NVP/ZDV for 14 weeks	• Postnatal infection in infants uninfected at birth: - MTCT at 6 weeks was 5.1% in control vs 1.7% in extended NVP (67% efficacy) and 1.6% in extended NVP/ZDV arms (69% efficacy). - MTCT at 9 months was 10.6% in control vs 5.2% in extended NVP (51% efficacy) and 6.4% in extended NVP/ZDV arms (40% efficacy). • No significant difference in MTCT between the extended prophylaxis arms; however, more hematologic toxicity with NVP/ZDV
MITRA Tanzania *[36]* Breastfeeding	Infant 3TC for 6 months (observational)	ZDV/3TC from 36 weeks through labor	Maternal ZDV/3TC for 1 week; infant 3TC for 6 months	• MTCT at 6 months was 4.9% (postnatal MTCT between 6 weeks and 6 months was 1.2%).
Kisumu Breastfeeding Study (KiBS) Kenya *[31]* Breastfeeding	Maternal triple drug prophylaxis (observational)	ZDV/3TC/NVP (NFV if CD4 >250) from 34 weeks through labor	Maternal ZDV/3TC/NVP (NFV if CD4 >250) for 6 months; infant sdNVP	• MTCT at 6 months was 5.0% (postnatal MTCT between 7 days and 6 months was 2.6%).
MITRA-PLUS Tanzania *[33]* Breastfeeding	Maternal triple drug prophylaxis (observational)	ZDV/3TC/NVP (NFV if CD4 >200) from 34 weeks through labor	Maternal ZDV/3TC/NVP (NFV if CD4 >200) for 6 months; infant ZDV/3TC for 1 week	• MTCT at 6 months was 5.0% (postnatal MTCT between 6 weeks and 6 months was 0.9%), not significantly different from 6 months infant prophylaxis in MITRA.

Kesho Bora Multi-African *[35]* Breastfeeding primarily	Antepartum ZDV/ sdNVP with no postnatal prophylaxis vs maternal triple drug prophylaxis in women with CD4 between 200 and 500	Arm 1: ZDV/3TC/LPV/r Arm 2: ZDV + sdNVP From 28 weeks through labor	Arm 1: Maternal ZDV/3TC/LPV/r for 6 months; infant sdNVP + ZDV for 1 week Arm 2: Maternal ZDV/3TC for 1 week (no further postnatal prophylaxis); infant sdNVP + ZDV for 1 week (no further postnatal prophylaxis)	• MTCT at birth was 1.8% with maternal triple drug prophylaxis Arm 1 and 2.2% with ZDV/sdNVP Arm 2, not significantly different. • MTCT at 12 months was 5.5% with maternal triple drug prophylaxis Arm 1 and 9.5% with ZDV/sdNVP (with no further postnatal prophylaxis after 1 week) Arm 2 (p=0.04).
Mma Bana Botswana *[34]* Breastfeeding	Maternal triple drug prophylaxis (compares 2 regimens) in women with CD4 >200	Arm 1: ZDV/3TC/ABC Arm 2: ZDV/3TC/LPV/r From 26 weeks through labor	Arm 1: Maternal ZDV/3TC/ABC for 6 months; infant sdNVP + ZDV for 4 weeks Arm 2: Maternal ZDV/3TC/LPV/r for 6 months; infant sdNVP + ZDV for 4 weeks	• MTCT at 6 months overall was 1.3%: 2.1% in ZDV/3TC/ABC Arm 1 and 0.4% in ZDV/3TC/LPV/r Arm 2 (p=0.53).
BAN Malawi *[32]* Breastfeeding	Postpartum maternal triple drug prophylaxis vs infant NVP in women with CD4 ≥250	No AP drugs IP regimens: Arm 1 (control): ZDV/3TC + sdNVP Arm 2: ZDV/3TC + sdNVP Arm 3: ZDV/3TC + sdNVP	Arm 1 (control): Maternal ZDV/3TC for 1 week; infant sdNVP + ZDV/3TC for 1 week Arm 2: Control as above, then maternal ZDV/3TC/LPV/r for 6 months Arm 3: Control as above, then infant NVP for 6 months	• Postnatal infection in infants uninfected at 2 weeks: - MTCT at 28 weeks was 5.7% in control Arm 1; 2.9% in maternal triple drug prophylaxis Arm 2 (p=0.009 vs control); 1.7% in infant NVP Arm 3 (<0.001 vs control). • No significant difference between maternal triple drug prophylaxis Arm 2 and infant NVP Arm 3 (p=0.12).

Key to Abbreviations: 3TC: lamivudine; ABC: abacavir; AP: antepartum; ARV: antiretroviral; CDC: Centers for Disease Control and Prevention; IP: intrapartum; LPV/r: lopinavir/ritonavir; MTCT: mother-to-child transmission; NFV: nelfinavir; NVP: nevirapine; PP: postpartum; sd: single-dose; ZDV: zidovudine

Preconceptional Counseling and Care for HIV-Infected Women of Childbearing Age

(Updated May 24, 2010)

Panel's Recommendations:

- ***Contraceptive counseling is an essential component of care for HIV-infected women of reproductive age and should include counseling on effective and appropriate contraceptive methods to reduce the likelihood of unintended pregnancy (AI).***
- ***Preconception counseling should include counseling on safe sexual practices and eliminating alcohol, illicit drug use, and smoking, which are important for the health of the woman as well as for fetal/infant health should pregnancy occur (AII).***
- ***Evaluation of the HIV-infected woman should include assessment of her HIV disease status and need for antiretroviral therapy for her own health (AII).***
- ***If already on therapy, her regimen should be reviewed in terms of potential pregnancy (e.g., teratogenic potential of the drugs in the regimen) (AII).***
- ***Choice of an antiretroviral treatment regimen for HIV-infected women of childbearing potential needs to include consideration of effectiveness for treatment of maternal disease, teratogenic potential of the drugs in the regimen should pregnancy occur, and possible adverse outcomes for mother and fetus (AII).***
- ***HIV-infected women who are on therapy and wish to become pregnant should attain a stable maximally suppressed viral load prior to conception (AIII).***

The Centers for Disease Control and Prevention (CDC), the American College of Obstetrics and Gynecology (ACOG), and other national organizations recommend offering all women of childbearing age the opportunity to receive preconception counseling and care as a component of routine primary medical care. The purpose of preconception care is to improve the health of each woman prior to conception by identifying risk factors for adverse maternal or fetal outcome, providing education and counseling targeted to the patient's individual needs, and treating or stabilizing medical conditions to optimize maternal and fetal outcomes *[1]*. Preconception care is not a single clinical visit but rather a process of ongoing care and interventions integrated into primary care to address the needs of women during the different stages of reproductive life. Because more than half of all pregnancies in the United States are unintended *[2-3]* it is important that preconception care be integrated into routine health visits. Therefore, HIV care providers who routinely care for women of reproductive age play an important role in promoting preconception health.

The fundamental principles of preconception counseling and care are outlined in the CDC Preconception Care Work Group's **Recommendations to Improve Preconception Health and Health Care**. In addition to the general components of preconception counseling and care that are appropriate for all women of reproductive age, HIV-infected women have specific needs that should be addressed *[4]*. Because many women infected with HIV are aware of their HIV status prior to pregnancy, issues that impact pregnancy may be addressed prior to conception during their routine medical care for HIV disease. In addition to those outlined by the CDC Preconception Care Work Group *[5]*, the following components of preconception counseling and care are specifically recommended for HIV-infected women. Health care providers should:

a. Offer all women effective and appropriate contraceptive methods to reduce the likelihood of unintended pregnancy. Providers should be aware of potential interactions of antiretroviral drugs with hormonal contraceptives that could lower contraceptive efficacy (see the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***, Tables 13, 14a, 14b) *[6]*.

b. Counsel on safe sexual practices that prevent HIV transmission to sexual partners, protect women from acquiring sexually transmitted infections (STIs), and reduce the potential to acquire more virulent or resistant HIV strains.

c. Counsel on eliminating alcohol, illicit drug use, and cigarette smoking.

d. Educate and counsel women about risk factors for perinatal transmission of HIV, strategies to reduce those risks, potential effects of HIV or treatment on pregnancy course and outcomes, and that breastfeeding by HIV-infected women is not recommended in the United States due to risk of HIV transmission and the availability of safe and sustainable infant feeding alternatives.

e. When prescribing antiretroviral treatment to women of childbearing potential, consider the regimen's effectiveness for treatment of HIV, hepatitis B disease status, the drugs' potential for teratogenicity should pregnancy occur, and possible adverse outcomes for mother and fetus *[7-8]*.

f. For women who are contemplating pregnancy, strongly consider the use of antiretroviral regimens that do not contain efavirenz or other drugs with teratogenic potential.

g. For women who are on antiretroviral therapy and want to get pregnant, set attaining a stable, maximally suppressed maternal viral load prior to conception as a primary treatment goal to decrease the risk of mother-to-child transmission of HIV.

h. Evaluate and appropriately manage therapy-associated side effects that may adversely impact maternal-fetal health outcomes (e.g., hyperglycemia, anemia, hepatic toxicity).

i. Evaluate the need for appropriate prophylaxis or treatment for opportunistic infections including safety, tolerability, and potential toxicity of specific agents when used in pregnancy.

j. Administer medical immunizations (e.g., influenza, pneumococcal, or hepatitis A and B vaccines) as indicated.

k. Encourage sexual partners to receive HIV testing and counseling and appropriate HIV care if infected.

l. Counsel regarding available reproductive options, such as intrauterine or intravaginal insemination, that prevent HIV exposure to an uninfected partner. Expert consultation is recommended *[9]*.

m. Counsel regarding available reproductive options to reduce risk of transmission to an uninfected female partner with an HIV-infected male partner; expert consultation is recommended *[10]*.

MONITORING OF PREGNANT WOMEN WITH A PARTNER KNOWN TO BE HIV INFECTED

Increasingly clinicians may be faced with the situation in which an HIV-uninfected woman presents during pregnancy and relates that she has an HIV-infected partner. As is recommended for all pregnant women, the woman should be notified that HIV screening is recommended and that she will receive an HIV test as part of the routine panel of prenatal tests unless she declines. In addition, she should receive a second HIV test during the third trimester, preferably before 36 weeks of gestation, as is recommended for high-risk women. Furthermore, if the pregnant woman presents in labor without third-trimester testing and result, then she should be screened with a rapid HIV test on the labor and delivery unit. If at any time during pregnancy the clinician suspects that a pregnant woman may be in the "window" period of seroconversion (i.e., has signs or symptoms consistent with acute HIV infection), then a plasma HIV RNA test can be used in conjunction with an HIV antibody test, and HIV testing may be repeated in 4–6 weeks. Women should be counseled regarding the symptoms of acute retroviral syndrome (i.e., fever, pharyngitis, rash, myalgia, arthralgia, diarrhea, headache) and the importance of seeking medical care and testing if they experience such symptoms.

If results from either conventional or rapid HIV testing are positive, then the woman should receive appropriate evaluation and interventions to reduce perinatal transmission of HIV, including immediate initiation of appropriate antiretroviral prophylaxis and consideration of elective cesarean delivery according to

established guidelines (see **Transmission and Mode of Delivery**). In cases where confirmatory testing results are not readily available (e.g., rapid testing during labor), it is appropriate to initiate interventions to reduce perinatal transmission even in the absence of confirmatory results (see **Infant Antiretroviral Prophylaxis**). If HIV testing results are negative, then pregnant women with HIV-infected partners should be regularly counseled regarding the ongoing risk of HIV transmission. If the partner's HIV status is at all uncertain, he should be encouraged to seek testing and appropriate care. All women and their partners should be counseled about the importance of correct and consistent condom use.

Antepartum Care (Updated May 24, 2010)

GENERAL PRINCIPLES REGARDING USE OF ANTIRETROVIRAL DRUGS DURING PREGNANCY

Panel's Recommendations:

- ***Initial evaluation of an infected pregnant woman should include an assessment of HIV disease status and recommendations regarding initiating antiretroviral therapy or altering her current antiretroviral regimen (AIII). The National Perinatal HIV Hotline (1-888-448-8765) provides free clinical consultation on all aspects of perinatal HIV care.***
- ***Antiretroviral prophylaxis for prevention of perinatal transmission of HIV during the antepartum period should be recommended to all pregnant, HIV-infected women regardless of plasma HIV RNA copy number or CD4 cell count (AI).***
- ***The known benefits and potential risks of antiretroviral use during pregnancy should be discussed with all women (AIII).***
- ***Zidovudine should be included in the antenatal antiretroviral regimen unless there is severe toxicity or documented resistance or the woman is already on a fully suppressive regimen (AIII).***
- ***If HIV RNA is detectable (e.g., >500–1,000 copies/mL), antiretroviral drug resistance studies should be performed before starting or modifying therapy (see Antiretroviral Drug Resistance and Resistance Testing in Pregnancy) (AI).***
- ***The importance of adherence to the antiretroviral treatment or prophylaxis regimen should be emphasized (AII).***
- ***Coordination of services among prenatal care providers, primary care and HIV specialty care providers, mental health and drug abuse treatment services, and public assistance programs, if necessary, should be assured as part of recommending antiretroviral drugs during pregnancy (AIII).***

In addition to the standard antenatal assessments for all pregnant women, the initial evaluation of an HIV-infected pregnant woman should include an assessment of HIV disease status and recommendations for HIV-related medical care. This initial assessment should include the following:

a. review of prior HIV-related illnesses, past CD4+ cell counts, and past plasma HIV viral loads;

b. current CD4+ cell count;

c. current plasma HIV RNA copy number;

d. assessment of the need for prophylaxis against opportunistic infections such as *Pneumocystis jirovecii* pneumonia (PCP) or *Mycobacterium avium* complex (MAC) *[1];*

e. baseline complete blood cell count and renal and liver function testing;

f. history of prior and current antiretroviral therapy;

g. history of prior antiretroviral drug use for prevention of perinatal HIV transmission;

h. results of prior and current HIV antiretroviral drug resistance studies; and

i. assessment of supportive care needs.

In general, guidelines for the use of antiretroviral drug treatment for the benefit of maternal health during pregnancy are the same as guidelines for women who are not pregnant. Antiretroviral prophylaxis is recommended for all pregnant women with HIV infection, regardless of viral load (see **HIV-Infected Pregnant Women Not on Antiretroviral Therapy Who Require Antiretroviral Prophylaxis Solely to Prevent Perinatal HIV Transmission**).

Decisions regarding initiating or altering antiretroviral drug regimens during pregnancy include considerations regarding the benefits and risks of antiretroviral drug use that are common to all HIV-infected adults in addition to considerations unique to pregnancy. Maternal toxicities and risks of therapy must be considered, along with the additional considerations of the potential impact of such therapy on the outcome of pregnancy and on the fetus and infant. These decisions are further complicated because there are only limited data on the long-term maternal consequences of antiretroviral drug use during pregnancy solely for prophylaxis of transmission. Similarly, there are only limited data on the long-term consequences of *in utero* antiretroviral exposure for the infant. The potential for drug-associated teratogenicity, toxicity, or the lack of data on specific drugs in pregnancy are important considerations in terms of drug regimen choice in a pregnant woman (**Table 3**).

Discussion of antiretroviral use with a pregnant woman should be noncoercive, and the final decision regarding use of antiretroviral drugs is the responsibility of the woman. The known benefits and known and unknown risks of antiretroviral drug use during pregnancy should be considered and discussed (see **Special Considerations Regarding the Use of Antiretroviral Drugs by HIV-infected Pregnant Women and their Infants**). Results from preclinical and animal studies and available clinical information about use of the various agents during pregnancy should be discussed with the woman (**Table 4** and **Table 5**). Potential risks of these drugs should be placed into perspective by also discussing substantial benefits of antiretroviral drugs for the health of the infected woman and for reducing the risk of HIV transmission to her infant.

Discussion with the woman about initiation of antiretroviral therapy should include the following:

a. maternal risk of disease progression and the benefits and risks of initiation of therapy for her own health;

b. benefit of combination antiretroviral regimens for preventing perinatal HIV transmission *[2]*;

c. Potential adverse effects of antiretroviral drugs for mother, fetus, and infant;

d. the limited long-term outcome data for both infants with *in utero* antiretroviral exposure and for women who temporarily use antiretroviral drugs during pregnancy for prophylaxis of transmission; and

e. the possibility of development of antiretroviral resistance, including the need for strict adherence to the prescribed drug regimen to avoid its development.

Although zidovudine should be a component of the antenatal antiretroviral regimen, there may be circumstances, such as the occurrence of severe zidovudine-related toxicity (e.g., severe anemia) or documented zidovudine resistance, when this is not possible. Additionally, women receiving an antiretroviral regimen that does not contain zidovudine but who have HIV RNA levels that are undetectable have a very low risk of perinatal transmission *[3]*, and there may be concerns that substitution of zidovudine for another component of the regimen or the addition of zidovudine to the current regimen could compromise adherence to treatment. In such cases, continuing a non-zidovudine-containing regimen that is fully suppressive is reasonable.

If plasma HIV RNA is detectable (greater than 500 to 1,000 copies/mL), antiretroviral drug resistance studies should be performed before starting antiretroviral therapy for maternal health or prophylaxis. However, if HIV is diagnosed late in pregnancy, therapy or prophylaxis should be initiated while

awaiting results of resistance testing (see **Antiretroviral Drug Resistance and Resistance Testing in Pregnancy**).

The importance of adherence to the antiretroviral treatment or prophylaxis regimen should be emphasized. Depending on individual circumstances, provision of support services, mental health services, and drug abuse treatment may be required. Coordination of services among prenatal care providers, primary care and HIV specialty care providers, mental health and drug abuse treatment services, and public assistance programs is essential to ensure adherence of the infected woman to the antiretroviral treatment regimen. Long-range plans should be developed with the woman regarding continuity of medical care and decisions about antiretroviral therapy for her own health after the birth of her infant.

Medical care of the HIV-infected pregnant woman requires coordination and communication between HIV specialists and obstetrical providers. General counseling should include current knowledge regarding risk factors for perinatal transmission. Potentially modifiable factors including cigarette smoking, illicit drug use, genital tract infections, and unprotected sexual intercourse with multiple partners during pregnancy have been associated with risk of perinatal HIV transmission *[4-8]*. In addition to improving maternal health, cessation of cigarette smoking and drug use, treatment of genital tract infections, and use of condoms with sexual intercourse during pregnancy may reduce risk of perinatal transmission. In addition, the CDC recommends that HIV-infected women in the United States (including those receiving antiretroviral therapy) refrain from breastfeeding to avoid postnatal transmission of HIV to their infants through breast milk *[9]*.

The National Perinatal HIV Hotline (1-888-448-8765)

The National Perinatal HIV Hotline is a federally funded service providing free clinical consultation to providers caring for HIV-infected women and their infants.

RECOMMENDATIONS FOR USE OF ANTIRETROVIRAL DRUGS DURING PREGNANCY

The Panel recommends that choice of antiretroviral drug regimens for HIV-infected pregnant women be based on the same principles used to choose regimens for non-pregnant individuals, unless there are compelling pregnancy-specific maternal or fetal safety issues regarding specific drug choices. The Panel reviews clinical trial data published in peer-reviewed journals and data prepared by manufacturers for FDA review related to treatment of HIV-infected adult women, both pregnant and nonpregnant. The durability, tolerability, and simplicity of the medication regimen is of particular importance in order to preserve options in the future for those women who will be stopping medications following delivery and for those women who meet standard criteria for initiation of antiretroviral therapy per adult guidelines and will continue the regimen after pregnancy. Regimen selection should be individualized and should consider a number of factors including:

- comorbidities,
- patient adherence potential,
- convenience,
- potential adverse drug effects on the mother,
- potential drug interactions with other medications,
- results of genotypic resistance testing,
- pharmacokinetic (PK) changes in pregnancy, and
- potential teratogenic effects on the fetus and other adverse effects on the fetus or newborn.

Criteria used by the Panel for recommending specific drugs or regimens for pregnant women include:

- Data from randomized prospective clinical trials that demonstrate durable viral suppression as well as immunologic and clinical improvement;
- Incidence rates and descriptions of short- and long-term drug toxicity of antiretroviral regimens with special attention to maternal toxicity and safety and teratogenic effects on the fetus;
- Specific knowledge about drug tolerability and simplified dosing regimens;
- Drug regimens that are known to be effective in reducing transmission to the fetus;
- Pharmacokinetic data during the prenatal period: The physiologic changes of pregnancy have the potential to alter the pharmacokinetics of drugs. Antiretroviral dosing during pregnancy should be based on pharmacokinetic data from studies in pregnant women. Physiologic changes are not fixed throughout pregnancy but rather reflect a continuum of change as pregnancy progresses, with return to baseline at various rates in the postpartum period.

Categories of antiretroviral regimens include:

- ***Preferred:*** Drugs or drug combinations are designated as preferred for use in pregnant women when clinical trial data in adults have demonstrated optimal efficacy and durability with acceptable toxicity and ease of use; pregnancy-specific pharmacokinetic data are available to guide dosing; and no evidence of teratogenic effects on the fetus or established association with teratogenic or clinically significant adverse outcomes for the mother, fetus, or newborn are present.

- ***Alternative:*** Drugs or drug combinations are designated as alternatives for initial therapy in pregnant women when clinical trial data in adults show efficacy but any one or more of the following conditions apply: there is limited experience in pregnancy; there is lack of data on teratogenic effects on the fetus; or there are dosing, formulation, administration, or interaction issues for that drug or regimen.

- ***Use in Special Circumstances:*** Drug or drug combinations in this category can be considered for use when intolerance or resistance prohibits use of other drugs with fewer toxicity concerns or the woman has comorbidities or requires concomitant medications that may limit drug choice (e.g., chronic hepatitis B infection, active tuberculosis requiring rifampin therapy).

- ***Not Recommended:*** Drugs and drug combinations listed in this category are not recommended for therapy in pregnant women because of inferior virologic response, potential serious safety concerns for the mother or fetus, or pharmacologic antagonism.

- ***Insufficient Data to Recommend:*** Although approved for use in adults, the drugs and drug combinations in this category do not have pregnancy-specific pharmacokinetic or safety data available or such data are too limited to make a recommendation for use for pregnancy.

All women who receive antiretroviral drugs during pregnancy either for treatment or prophylaxis should receive combination regimens containing at least three agents. A combination regimen including two nucleoside reverse transcriptase inhibitors (NRTIs) and either a non-nucleoside reverse transcriptase inhibitor (NNRTI) or a protease inhibitor (PI) (with or without low-dose ritonavir) should be used. The preferred NRTI regimen in pregnancy, based on efficacy studies in preventing perinatal transmission (see **Lessons from Clinical Trials of Antiretroviral Interventions to Reduce Perinatal HIV Transmission**) and large experience with use in pregnancy, is zidovudine/lamivudine. Alternate regimens may be used for women who have intolerance of zidovudine because of toxicity such as severe anemia or with known resistance to zidovudine. Tenofovir, a preferred NRTI in nonpregnant women, should be used only in special circumstances (such as intolerance or resistance to zidovudine or chronic hepatitis B infection) because of concerns regarding the potential for fetal toxicity. Animal studies have shown decreased fetal growth and reduction in fetal bone porosity, and studies in infected children on chronic tenofovir-based therapy have shown bone demineralization in some children. The combination of stavudine/didanosine should not be used in pregnant women because of fatal cases of lactic acidosis and hepatic failure reported in pregnant women who received this combination throughout pregnancy.

In addition to the two NRTIs, either an NNRTI or a PI should be included in antiretroviral regimens prescribed for maternal health. Efavirenz, the preferred NNRTI for nonpregnant adults, is not recommended for use in the first trimester of pregnancy because of animal data showing risk of anencephaly, micro-ophthalmia, and facial clefts as well as concerning case reports of several neural tube defects and a single case of anophthalmia with severe facial cleft in humans. Use of efavirenz after the first trimester of pregnancy may be considered if alternate agents are not tolerated. Nevirapine may be used in women with CD4+ lymphocyte counts less than 250 cells/mm^3 or continued for women already receiving a nevirapine-based regimen. Nevirapine should generally not be initiated for treatment-naïve women with CD4+ cell counts greater than 250 cells/mm^3 because of an increased risk of symptomatic and potentially fatal rash and hepatic toxicity. Etravirine has insufficient safety or pharmacokinetic data in pregnancy to recommend its use. Lopinavir/ritonavir is the preferred protease inhibitor regimen for pregnant women because of efficacy studies in adults and experience with use in pregnancy (see **Table 5** for dosing considerations). Alternative protease inhibitors include ritonavir-boosted atazanavir, saquinavir, or indinavir, although experience with these regimens in pregnancy is more limited and the latter two may be less well tolerated. Data on use in pregnancy for darunavir, fosamprenavir, and tipranavir are too limited to recommend routine use in pregnancy, although they may be considered if other agents are not tolerated.

Safety and pharmacokinetics data in pregnancy are insufficient to recommend use of the entry inhibitors enfuvirtide and maraviroc and the integrase inhibitor raltegravir during pregnancy. Use of these agents for women who have failed therapy with several other classes of antiretroviral drugs could be considered in consultation with HIV and obstetric specialists.

In addition, recommendations for the use of antiretroviral drugs for prophylaxis to prevent perinatal HIV transmission in women for whom therapy would not otherwise be indicated include the agents/combinations discussed above and some that are not considered preferred regimens in nonpregnant adults, such as triple NRTI regimens with abacavir and the use of nelfinavir with two NRTIs. These options are discussed in more detail below.

Although data are insufficient to support or refute the teratogenic risk of antiretroviral drugs when administered during the first 10 weeks of gestation, information to date does not support major teratogenic effects of the majority of antiretroviral drugs. (For further data, see **www.APRegistry.com**.) However, certain drugs are of more concern than others (**Table 4** and see **Teratogenicity** and **Supplement: Safety and Toxicity of Individual Antiretroviral Drugs in Pregnancy**). For example, efavirenz should be avoided during the first trimester of pregnancy.

Recommendations for antiretroviral therapy during pregnancy must be individualized according to the specific antiretroviral history of the HIV-infected pregnant woman. Some women may be receiving antiretroviral therapy for their own health at the time they become pregnant and present for obstetrical care on such therapy. Other HIV-infected women may not be receiving antiretroviral therapy at the time they present for obstetrical care. Some of these women have never received antiretroviral drugs before, while other women may have previously received antiretroviral drugs, either for treatment that was stopped or for prophylaxis to prevent perinatal HIV transmission in prior pregnancies. Considerations for initiating therapy will differ for such women according to whether antiretroviral drugs are currently indicated for maternal health or solely for fetal protection. The antiretroviral recommendations below are divided into sections according to antiretroviral treatment status at the time the woman presents for care and whether there are maternal indications for therapy.

Table 5 provides recommendations about the use of specific antiretroviral drugs in pregnancy as well as data on pharmacokinetics and toxicity in pregnancy. **Table 6** provides a summary of management recommendations for the mother and infant in a variety of clinical scenarios.

HIV-Infected Pregnant Women Who Are Currently Receiving Antiretroviral Treatment

Panel's Recommendations:

- ***Pregnant women receiving and tolerating an antiretroviral treatment regimen that is currently effective in suppressing viral replication should continue on the regimen; however, the use of efavirenz should be avoided in the first trimester of pregnancy (AIII).***
- ***HIV antiretroviral drug resistance testing is recommended if the pregnant woman has detectable viremia (e.g., >500–1,000 copies/mL) on therapy (see Failure of Viral Suppression) (AI).***
- ***Pregnant women receiving nevirapine-containing regimens who are virologically suppressed and tolerating the regimen should continue the regimen, regardless of CD4 count (AIII).***

In general, women who have been receiving antiretroviral treatment for their HIV infection should continue treatment during pregnancy. Discontinuation of therapy could lead to an increase in viral load with possible decline in immune status and disease progression as well as adverse consequences for the fetus, including increased risk of HIV transmission. Therefore, when pregnancy is identified after the first trimester in HIV-infected women receiving antiretroviral therapy at the time of conception, therapy should always be continued.

HIV-infected women receiving antiretroviral treatment who present for care during the first trimester of pregnancy should be counseled regarding the benefits and potential risks of antiretroviral administration during this period, and continuation of therapy should be recommended. However, the use of efavirenz should be avoided during the first trimester of pregnancy. If a woman is receiving efavirenz and her pregnancy is recognized during the first trimester, an alternative antiretroviral drug should be substituted when possible (see **Monitoring of the Woman and Fetus during Pregnancy**).

Resistance testing should be performed in women who are on therapy but not fully suppressed. Results of this testing can be used to select a regimen that may have greater chance to suppress viral loads to undetectable. It should be noted that resistance assays vary depending on the HIV RNA level required to detect resistance mutations. Some assays require HIV RNA levels of ≥1,000 copies/mL; other assays can be performed with lower viral loads.

Pregnant women who are receiving nevirapine-containing regimens with viral suppression and are tolerating the regimen well should continue therapy, regardless of CD4 count. Although hepatic toxicity is a concern in women who have a CD4 count >250 cells/mm^3 when they first start a nevirapine-containing regimen, an increased risk of hepatic toxicity has not been seen in women who are receiving nevirapine-based therapy and have immune reconstitution with therapy.

HIV-Infected Pregnant Women Who Have Never Received Antiretroviral Drugs (Antiretroviral Naïve)

Panel's Recommendations:

- ***HIV-infected pregnant women who meet standard criteria for initiation of antiretroviral therapy per adult antiretroviral treatment guidelines should receive standard potent combination antiretroviral therapy as recommended for nonpregnant adults, taking into account what is known about the use of specific drugs in pregnancy and risk of teratogenicity (Table 5) (AI).***
  - ***For women who require immediate initiation of therapy for their own health, treatment should be started as soon as possible, including in the first trimester of pregnancy (AII). (Note that the use of efavirenz should be avoided during the first trimester.)***
- ***HIV-infected pregnant women who do not require treatment for their own health should also receive three-drug combination antiretroviral regimens for prophylaxis of perinatal transmission (AII). The use of zidovudine alone as prophylaxis is controversial but may be considered for those women initiating prophylaxis with plasma HIV RNA levels <1,000 copies/mL on no therapy (CII).***
  - ***For women who are receiving antiretroviral drugs solely for prevention of perinatal transmission, delaying initiation of prophylaxis until after the first trimester of pregnancy can be considered (BIII).***
- ***Zidovudine should be used as a component of the antiretroviral regimen when feasible (AIII).***
- ***HIV antiretroviral drug resistance testing should be performed prior to initiating antiretroviral prophylaxis or therapy (AI)*.***
- ***Nevirapine may be used as a component of initial therapy for pregnant women with CD4 cell counts <250 cells/mm^3. However, due to an increased risk of hepatic toxicity, nevirapine should only be used as a component of antiretroviral therapy in pregnant women with CD4 cell counts >250 cells/mm^3 if the benefit clearly outweighs the risk (AII).***

**Dependent on the resistance assay being used; some assays require HIV RNA levels of ≥1,000 copies/mL for performance of the resistance assay, while other assays can be used with lower levels of viral replication.*

Pregnant women with HIV infection should receive standard clinical, immunologic, and virologic evaluation. Decisions about the need for initiation of therapy should be based on the standard guidelines for nonpregnant adults *[10]*.

HIV-Infected Pregnant Women Not on Antiretroviral Therapy and Who Need Antiretroviral Treatment for Their Own Health

Any HIV-infected pregnant woman who meets standard criteria for initiation of antiretroviral therapy as per adult antiretroviral guidelines should receive potent combination antiretroviral therapy, generally consisting of NRTIs plus an NNRTI or PIs, with continuation of therapy postpartum. For women who require immediate initiation of therapy for their own health, treatment should be started as soon as possible, including in the first trimester, because the potential benefit of treatment for the mother outweighs potential fetal risks. The regimen should generally be chosen from those recommended for nonpregnant adults (e.g., a preferred or alternative regimen), taking into account what is known about use of the drugs during pregnancy and risk of teratogenicity (see **Table 5** and **Teratogenicity**) *[10]*.

Women with CD4 counts >250 cells/mm^3 have an increased risk of developing symptomatic, often rash-associated, nevirapine-related hepatotoxicity that can be severe, life-threatening, and in some cases fatal *[11-12]*. Therefore, nevirapine should only be used as a component of a combination regimen when antiretroviral therapy is being initiated in women with CD4 counts >250 cells/mm^3 if the benefit clearly outweighs the risk. If nevirapine is used, frequent and careful monitoring of

transaminase levels, particularly during the first 18 weeks of treatment, is required (see **Nevirapine and Hepatic/Rash Toxicity**). Transaminase levels should be checked in all women who develop a rash while receiving nevirapine. Nevirapine should be stopped immediately in all women who develop signs or symptoms of hepatitis.

HIV-Infected Pregnant Women Not on Antiretroviral Therapy Who Require Antiretroviral Prophylaxis Solely to Prevent Perinatal HIV Transmission

HIV-infected pregnant women should be counseled regarding the benefits of antiretroviral drugs for prevention of perinatal transmission even when initiation of antiretroviral therapy for maternal health is not recommended or is considered optional on the basis of current guidelines for treatment of nonpregnant persons *[10]*. Although such women are at low risk of clinical disease progression if antiretroviral treatment is delayed, use of an antiretroviral regimen that successfully reduces plasma HIV RNA to undetectable levels substantially lowers the risk of perinatal HIV transmission and lessens the need for consideration of elective cesarean delivery as an intervention to reduce transmission risk.

Because the fetus is most susceptible to the potential teratogenic effects of drugs during the first 10 weeks of gestation and the risks of antiretroviral therapy during that period are not fully known, women in the first trimester of pregnancy who do not require immediate initiation of therapy for their own health may consider delaying initiation until after 10 to 12 weeks gestation. This decision should be carefully considered by the health care provider and the woman; a discussion should include an assessment of the woman's health status, the benefits and risks to her of delaying initiation of therapy for several weeks, and the fact that most perinatal HIV transmission likely occurs late in pregnancy or during delivery.

Antiretroviral prophylaxis is recommended for all pregnant women with HIV infection, regardless of viral load. Although rates of perinatal transmission are low in women with undetectable or low HIV RNA levels (e.g., <1,000 copies/mL), there is no threshold below which lack of transmission can be assured *[2, 13-14]*. The mechanism by which antiretroviral drugs reduce perinatal HIV transmission is multifactorial. Although lowering maternal antenatal viral load is an important component of prevention in women with higher viral load, antiretroviral prophylaxis is effective even in women with low viral load *[15-19]*. Additional mechanisms of protection include pre-exposure prophylaxis of the infant, provided by passage of the antiretroviral drug across the placenta so that inhibitory levels of drug are present in the fetus particularly during the birth process, and post-exposure prophylaxis through continued administration to the infant. Although placental passage of zidovudine is excellent, that of many other antiretroviral drugs may be variable (**Table 4**). Therefore, when combination antiretroviral therapy is initiated during pregnancy, zidovudine should be included as a component of antenatal therapy whenever possible. If antenatal zidovudine use is not possible, at least one agent with known transplacental passage should be part of the antiretroviral regimen (see **Table 4**).

Combination antiretroviral regimens containing at least three drugs for prevention of perinatal HIV transmission should be discussed and offered to all pregnant women with HIV infection. A number of studies suggest that antenatal use of combination antiretroviral regimens further reduces transmission compared to use of zidovudine alone. In a longitudinal epidemiologic study conducted in the United States since 1990, transmission was observed in 20% of women with HIV infection who received no antiretroviral treatment during pregnancy, 10.4% who received zidovudine alone, 3.8% who received combination therapy without protease inhibitors (primarily dual NRTIs), and 1.2% who received combination therapy with protease inhibitors *[2]*. However, in these older studies, zidovudine alone was often used in women with higher viral load and lower CD4, in whom treatment would now be recommended. In more recent data from the United Kingdom and Ireland, perinatal transmission occurred among 9.1% of women who received no antiretroviral drugs, 0.5% of women who received single drug prophylaxis (primarily zidovudine, as recommended by U.K. guidelines for women with HIV RNA levels less than 10,000 copies/mL), 0.8% of women who received dual drug prophylaxis,

and 1.0% of women who received triple drug regimens for treatment or prophylaxis. There were no significant differences in transmission rate between the drug regimen groups; the majority of women in all groups were delivered by scheduled cesarean delivery. Among 2,117 infants born to women on triple drug combination antiretroviral therapy or prophylaxis with HIV RNA less than 50 copies/mL at delivery, only 0.1% were infected *[20]*.

A three-drug combination antiretroviral regimen not regarded as one of the standard first-line regimens recommended for adults who require therapy may be considered for the pregnant woman if the regimen is given solely to reduce perinatal transmission, is only needed because the woman is pregnant, and will be discontinued postpartum. The triple NRTI combination zidovudine/lamivudine/abacavir regimen may be considered because of known pharmacokinetic profiles and published data suggesting acceptable toxicities during pregnancy. Testing for HLA-B*5701 identifies patients at risk of hypersensitivity reactions *[21-22]* and should be done and documented as negative before starting abacavir. Triple drug regimens containing the PI nelfinavir, which is not part of standard first-line therapy, may also be considered because there is a large experience with its safe use during pregnancy. However, these regimens have inferior long-term virologic efficacy, and for women with high CD4 counts but high viral load (i.e., CD4 count >350/mm^3 and HIV RNA >100,000 copies/mL), the use of first-line, more potent regimens should be considered. Dual NRTI therapy without the addition of a third drug (i.e., a PI, NNRTI, or a third NRTI) is not recommended because of the potential for inadequate viral suppression and rapid development of resistance *[10, 23]*.

The time-limited use of zidovudine alone during pregnancy for chemoprophylaxis against perinatal transmission is controversial. However, some women who may wish to restrict exposure of their fetus to antiretroviral drugs during pregnancy while still reducing the risk of transmitting HIV to their infants may opt for use of zidovudine alone. Additionally, for women with low viral load, time-limited use of zidovudine during the second and third trimesters of pregnancy is less likely to induce the development of resistance than in women with higher viral loads because of the low level of viral replication in the virologically suppressed women and the short duration of exposure to the antiretroviral drug *[24-25]*. For example, the development of zidovudine resistance was unusual among the healthy population of women who participated in PACTG 076 *[26]*. Thus, although controversial, the use of zidovudine chemoprophylaxis alone during pregnancy might be an appropriate option for this subset of women (i.e., women with HIV RNA levels <1,000 on no treatment).

In general, if antiretroviral drugs are given solely for prevention of perinatal HIV transmission, the antiretroviral drugs are discontinued postnatally, with the option to reinitiate standard potent treatment regimens in the future according to the usual criteria for nonpregnant individuals. Discussion regarding the decision to continue or stop antiretrovirals postpartum should occur before beginning antiretrovirals during pregnancy. Generally, when drugs are discontinued postnatally, all drugs should be stopped simultaneously. However, as discussed later (see **Stopping Antiretroviral Therapy during Pregnancy**), in women receiving NNRTI-based regimens, continuing the dual NRTI backbone for a period of time after stopping the NNRTI should be considered to reduce the development of NNRTI resistance. An alternative strategy is to replace the NNRTI with a PI drug while continuing the NRTIs, then to discontinue all the drugs at the same time *[27]*. The optimal interval between stopping an NNRTI and the other antiretroviral drugs is not known; at least 7 days is recommended. In patients receiving an efavirenz-based NNRTI regimen after the first trimester, detectable drug concentrations may be observed for more than 3 weeks after stopping efavirenz. Therefore, some experts recommend continuing the other antiretroviral agents or substituting a PI plus two other agents for up to 30 days in such patients.

HIV-Infected Pregnant Women Who Have Previously Received Antiretroviral Treatment or Prophylaxis but Are Not Currently Receiving Any Antiretroviral Medications

Panel's Recommendations:

- ***Obtain an accurate history of all prior antiretroviral regimens used for treatment of HIV disease or prevention of transmission and results of prior resistance testing (AIII).***
- ***Perform HIV antiretroviral drug resistance testing prior to initiating repeat antiretroviral prophylaxis or therapy (AI).***
- ***Initiate a combination antiretroviral drug regimen, with regimen chosen based on resistance testing and prior antiretroviral therapy history, and avoid drugs with teratogenic potential (efavirenz in the first trimester of pregnancy) or with known adverse potential for the pregnant mother (e.g., combination stavudine/didanosine) (AII).***
- ***Women who do not show an appropriate virologic response to their antiretroviral regimens (see Monitoring of the Woman and Fetus During Pregnancy) require repeat antiretroviral drug resistance testing (AI), as well as consultation with a clinician experienced in HIV treatment, to guide changes in antiretroviral therapy.***

There are no data to guide the choice of antiretroviral regimens to be used in a subsequent pregnancy for women who previously received antiretroviral prophylaxis for prevention of perinatal HIV transmission. Although there is concern that time-limited use of antiretroviral drugs during pregnancy may lead to genotypic resistance, reduced efficacy of standard regimens, particularly those containing the dual NRTI backbone of zidovudine and lamivudine, in successive pregnancies has not been demonstrated. Given the lack of substantive data, it is reasonable to make preliminary decisions about antiretroviral regimens based on results of initial resistance testing. However, interpretation of resistance testing following discontinuation of antiretroviral drugs can be complex because the assay may not detect low-level drug-resistant viral variants. Thus, careful monitoring of virologic response to the chosen antiretroviral regimen is important. Decisions to alter therapy based on lack of virologic response should be guided by repeat resistance testing.

Some women may have received antiretroviral treatment for their own health in the past, having discontinued the drugs for a variety of reasons and for variable lengths of time prior to pregnancy. Appropriate choice of antiretroviral drugs will vary according to the history of antiretroviral use, the indication for stopping therapy, and the results of past and current resistance testing. For example, women with a history of prior antiretroviral therapy associated with successful suppression of viral load who then stopped all drugs simultaneously (or staggered discontinuation if NNRTI based) and who have no evidence of resistance may be able to restart the same regimen. Alternatively, selection of an appropriate antiretroviral regimen for women with advanced HIV disease, a history of extensive prior antiretroviral therapy, or history of significant toxicity to antiretroviral drugs in the past may be challenging even for health care providers experienced in HIV care. In addition to obtaining genotypic resistance testing as described above, it is recommended that specialists in the treatment of HIV infection be consulted about the choice of antiretroviral therapy in such cases.

Table 4. Preclinical and Clinical Data Relevant to the Use of Antiretrovirals in Pregnancy (See *Supplement: Safety and Toxicity of Individual Antiretroviral Agents in Pregnancy* for more detail on drugs.)

Antiretroviral Generic name (Abbreviation)/ Trade name	FDA Pregnancy Category *	Placental Passage Newborn: Mother Drug Ratio	Long-term Animal Carcinogenicity Studies	Animal Teratogenicity Studies
Nucleoside and nucleotide analogue reverse transcriptase inhibitors				
Abacavir (ABC)/ Ziagen	C	Yes (rats)	Positive (malignant and non-malignant tumors of liver and thyroid in female rats and preputial and clitoral glands in mice and rats at 6–32x human exposure)	Positive (rodent anasarca and skeletal malformations at 1,000 mg/kg [35x human exposure] during organogenesis; not seen at 8.5x human exposure in rabbits)
Didanosine (ddI)/ Videx	B	Yes (humans) 0.5	Negative (no tumors in lifetime rodent study at 0.7–3x maximum human exposure)	Negative (at 12x and 14.2x human exposure in rabbits and rats, respectively)
Emtricitabine (FTC)/ Emtriva	B	Yes (mice and rabbits) 0.4–0.5	Negative (no tumors in lifetime rodent study at 26–31x human exposure)	Negative (at 60x, 60x, and 120x human exposure in rats, mice, and rabbits, respectively)
Lamivudine (3TC)/ Epivir	C	Yes (humans) ~1.0	Negative (no tumors in lifetime rodent study at 10–58x human exposure)	Negative (at 35x human exposure in rats and rabbits; however, embryolethality seen in rabbits at 1x human exposure)
Stavudine (d4T)/ Zerit	C	Yes (rhesus monkeys) 0.76	Positive (in mice and rats at very high dose exposure; liver and bladder tumors [rats only] at 250x and 732x human exposure in mice and rats, respectively)	Negative (at 399x [rats] and 183x [rabbits] human exposure, although sternal bone ossification decreased and rat neonatal mortality increased at 399x human exposure in rats)
Tenofovir DF (TDF)/ Viread	B	Yes (humans) 0.95–0.99	Positive (hepatic adenomas in female mice only at 16x human exposure)	Negative (at 14x and 19x human exposure in rats and rabbits, respectively)
Zidovudine (AZT, ZDV)/ Retrovir	C	Yes (humans) 0.85	Positive (nonmetastasizing vaginal epithelial tumors at 3x and 24x human exposure in mice and rats, respectively)	Positive (increased fetal malformations associated with maternal toxicity at 300x human exposure in rats. Increased fetal resorptions at 66–226x and 12–87x human exposure in rats and rabbits, respectively, with no developmental abnormalities)
Non-nucleoside reverse transcriptase inhibitors				
Efavirenz (EFV)/ Sustiva	D	Yes (cynomolgus monkeys, rats, rabbits) ~1.0	Positive (hepatocellular adenomas and carcinomas and pulmonary alveolar/bronchiolar adenomas in female mice at 1.7x human exposure; no increases in tumors in rats at 0.2x human exposure)	Positive (anencephaly, anophthalmia, microophthalmia, and cleft palate in cynomolgus monkey at exposures comparable to human exposure; no reproductive toxicities in pregnant rabbits at 0.5–1x human exposure)

Antiretroviral Generic name (Abbreviation)/ Trade name	FDA Pregnancy Category *	Placental Passage Newborn: Mother Drug Ratio	Long-term Animal Carcinogenicity Studies	Animal Teratogenicity Studies
Non-nucleoside reverse transcriptase inhibitors (cont)				
Etravirine (ETR)/ Intelence	B	Unknown	Positive (hepatocellular adenomas and carcinomas in female mice at 0.6x human exposure; no findings in rats at 0.2–0.7x human exposure)	Negative (in rats and rabbits at exposures comparable to human exposures)
Nevirapine (NVP)/ Viramune	B	Yes (humans) ~1.0	Positive (hepatocellular adenomas and carcinomas in mice and rats at less than human exposure)	Negative (in rats and rabbits at 1–1.5x human exposure; however, decreased fetal body weight in rats at 1.5x human exposure)
Protease inhibitors				
Atazanavir (ATV)/ Reyataz	B	Minimal/variable (humans)	Positive (benign hepatocellular adenomas in female mice at 7.2x human exposure)	Negative (at 2x and 1x human exposure in rats and rabbits, respectively)
Darunavir (DRV)/ Prezista	C	Unknown	Positive (hepatic adenomas, carcinomas [male mice], thyroid neoplasms [rats only] at 0.1–0.3x and 0.7–1x human exposure in mice and rats, respectively)	Negative (at 0.5x and 0.05x human exposure in rats/mice and rabbits, respectively)
Fosamprenavir (f-APV)/ Lexiva)	C	Unknown	Positive (hepatic adenomas and carcinomas [mice and rats]; thyroid adenomas, interstitial cell hyperplasia, and uterine endometrial adenocarcinoma [rats only] at 0.1–0.7x and 0.3–1.4x human exposure in mice and rats, respectively	Negative (at 0.8x and 2x human exposure in rabbits and rats respectively; increased incidence of abortions in rabbits at 0.8x human exposure)
Indinavir (IDV)/ Crixivan	C	Minimal (humans)	Positive (thyroid adenomas in male rats at 1.3x human exposure)	Negative (however supernumerary ribs in rats at exposures less than or slightly greater than human exposure)
Lopinavir + Ritonavir (LPV/r)/ Kaletra)	C	Yes (humans) 0.20±0.13	Positive (hepatic adenomas and carcinomas at 1.6–2.2x and 0.5x human exposure in mice and rats, respectively)	Positive (no effects in rabbits and dogs at ~1x human exposure; decreased fetal viability and body weight, delayed skeletal ossification and increase in skeletal variations in rats at maternally toxic doses [at 0.7x and 1.8x human exposure for lopinavir and ritonavir, respectively])
Nelfinavir (NFV)/ Viracept	B	Minimal/variable (humans)	Positive (thyroid follicular adenomas and carcinomas at 1–3x human exposure in rats)	Negative (in rats at human exposure and in rabbits at significantly lower than human exposure)

Antiretroviral Generic name (Abbreviation)/ Trade name	FDA Pregnancy Category *	Placental passage Newborn: Mother Drug Ratio	Long-term Animal Carcinogenicity Studies	Animal Teratogenicity Studies
Protease inhibitors (cont)				
Ritonavir (RTV)/ Norvir	B	Minimal (humans)	Positive (hepatic adenomas and carcinomas in male mice at 0.3x human exposure)	Positive (early resorptions, decreased fetal body weight, ossification delays, and developmental variations in rats at maternally toxic dose [~0.3x human exposure]; cryptorchidism in rats at 0.22x human exposure)
Saquinavir (SQV) Invirase	B	Minimal (humans)	Negative (at 0.29x and 0.65x human exposure [coadministration with ritonavir] in rats and mice, respectively)	Negative (at 0.29x and 0.21x human exposure [coadministration with ritonavir] in rats and rabbits, respectively)
Tipranavir (TPV)/ Aptivus	C	Unknown	Positive (hepatic adenomas and carcinomas in mice at less than human exposure; thyroid follicular cell adenoma in female rats at exposures comparable to human exposure)	Negative (decreased ossification and pup weights in rats at 0.8x human exposure)
Entry inhibitors				
Enfuvirtide (T-20)/ Fuzeon	B	None (based on very limited human data)	Not conducted	Negative
Maraviroc (MVC)/ Selzentry	B	Unknown	Negative (in transgenic mice and rats at 11x human exposure)	Negative (at 20x and 5x human exposure in rats and rabbits, respectively)
Integrase inhibitors				
Raltegravir (RAL)/ Isentress	C	Yes (rats, rabbits) † Rats: 1.5–2.5 Rabbits: 0.02	In progress	Negative (however, supernumerary ribs in rats at 3x human exposure)

* Food and Drug Administration Pregnancy Categories:
A - Adequate and well-controlled studies of pregnant women fail to demonstrate a risk to the fetus during the first trimester of pregnancy (and no evidence exists of risk during later trimesters).
B - Animal reproduction studies fail to demonstrate a risk to the fetus, and adequate but well-controlled studies of pregnant women have not been conducted.
C - Safety in human pregnancy has not been determined; animal studies are either positive for fetal risk or have not been conducted, and the drug should not be used unless the potential benefit outweighs the potential risk to the fetus.
D - Positive evidence of human fetal risk that is based on adverse reaction data from investigational or marketing experiences, but the potential benefits from the use of the drug among pregnant women might be acceptable despite its potential risks.
X - Studies among animals or reports of adverse reactions have indicated that the risk associated with the use of the drug for pregnant women clearly outweighs any possible benefit.

† Values obtained from fetal (not newborn) blood samples. See text under "Placental and breast milk passage" in section on Raltegravir (Isentress) in ***Supplement: Safety and Toxicity of Individual Antiretroviral Agents in Pregnancy***.

Table 5. Antiretroviral Drug Use in Pregnant HIV-Infected Women: Pharmacokinetic and Toxicity Data in Human Pregnancy and Recommendations for Use in Pregnancy

(See also "Supplement: Safety and Toxicity of Individual Antiretroviral Drugs in Pregnancy" for additional toxicity data and "Guidelines for the Use of Antiretroviral Agents in HIV-1-infected Adults and Adolescents" for detailed guidelines regarding treatment options.)

Antiretroviral Drug	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Recommendations for Use in Pregnancy
NRTIs/ NtRTIs		See text for discussion of potential maternal and infant mitochondrial toxicity.	NRTIs are recommended for use as part of combination regimens, usually including two NRTIs with either an NNRTI or one or more PIs. Use of single or dual NRTIs alone is not recommended for treatment of HIV infection. (Zidovudine alone may be considered for prophylaxis of perinatal transmission in pregnant women with HIV RNA <1,000 copies/mL.)
Recommended Agents			
Lamivudine*	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated *[1]*.	No evidence of human teratogenicity (can rule out 1.5-fold increase in overall birth defects) *[2]*. Well-tolerated, short-term safety demonstrated for mother and infant. If hepatitis B coinfected, possible hepatitis B flare if drug stopped postpartum (see **Special Considerations: Hepatitis B Virus Coinfection**).	Because of extensive experience with lamivudine in pregnancy in combination with zidovudine, lamivudine plus zidovudine is the recommended dual NRTI backbone for pregnant women.
Zidovudine*	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated *[3]*.	No evidence of human teratogenicity (can rule out 1.5-fold increase in overall birth defects) *[2]*. Well-tolerated, short-term safety demonstrated for mother and infant.	Preferred NRTI for use in combination antiretroviral regimens in pregnancy based on efficacy studies and extensive experience. Zidovudine should be included in the antenatal antiretroviral regimen unless there is severe toxicity, stavudine use, documented resistance, or the woman is already on a fully suppressive regimen.
Alternate Agents			
Abacavir*	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Hypersensitivity reactions occur in ~5%–8% of nonpregnant persons; fatal reactions occur in a much smaller percentage of persons and are usually associated with rechallenge. Rate of hypersensitivity reactions in pregnancy is unknown. Testing for HLA-B*5701 identifies patients at risk of reactions *[4-5]* and should be done and documented as negative before starting abacavir. Patient should be educated regarding symptoms of hypersensitivity reaction.	Alternate NRTI for dual nucleoside backbone of combination regimens. See footnote regarding use in triple NRTI regimen. #
Didanosine	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated *[6]*.	Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving didanosine and stavudine together *[7-8]*.	Alternate NRTI for dual nucleoside backbone of combination regimens. Didanosine should be used with stavudine only if no other alternatives are available.

Antiretroviral Drug	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Recommendations for Use in Pregnancy
Alternate Agents (continued)			
Emtricitabine†	Pharmacokinetic study shows slightly lower levels in third trimester compared to postpartum *[9]*. No clear need to increase dose.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*.	Alternate NRTI for dual nucleoside backbone of combination regimens.
Stavudine	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated *[10]*.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving didanosine and stavudine together *[7-8]*.	Alternate NRTI for dual nucleoside backbone of combination regimens. Stavudine should be used with didanosine only if no other alternatives are available. Do not use with zidovudine due to potential for antagonism.
Use in Special Circumstances			
Tenofovir†	Limited studies in human pregnancy; data indicate AUC lower in third trimester than postpartum but trough levels similar.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Studies in monkeys at doses approximately 2-fold higher than dosage for human therapeutic use show decreased fetal growth and reduction in fetal bone porosity within 2 months of starting maternal therapy *[11]*. Clinical studies in humans (particularly children) show bone demineralization with chronic use; clinical significance unknown *[12-13]*. Significant placental passage in humans (cord:maternal blood ratio 0.6–0.99). If hepatitis B coinfected, possible hepatitis B flare if drug stopped postpartum (see **Special Considerations: Hepatitis B Virus Coinfection)**.	Because of limited data on use in human pregnancy and concern regarding potential fetal bone effects, tenofovir should be used as a component of a maternal combination regimen only after careful consideration of other alternatives. Because of potential for renal toxicity, renal function should be monitored.
NNRTIs		Hypersensitivity reactions, including hepatic toxicity, and rash more common in women; unclear if increased in pregnancy.	NNRTIs are recommended for use in combination regimens with 2 NRTI drugs.
Recommended Agents			
Nevirapine	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated *[14-15]*.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Increased risk of symptomatic, often rash-associated, and potentially fatal liver toxicity among women with CD4 counts >250/mm^3 when first initiating therapy *[16-17]*; unclear if pregnancy increases risk.	Nevirapine should be initiated in pregnant women with CD4 counts >250 cells/mm^3 only if benefit clearly outweighs risk, due to the increased risk of potentially life-threatening hepatotoxicity in women with high CD4 counts. Women who enter pregnancy on nevirapine regimens and are tolerating them well may continue therapy, regardless of CD4 count.

Antiretroviral Drug	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Recommendations for Use in Pregnancy
Use in Special Circumstances			
Efavirenz†	Small study in 13 breastfeeding women in Rwanda of 600 mg once daily; postpartum peak levels during lactation were 61% higher than previously reported in HIV-infected nonpregnant individuals at that dose *[18]*.	FDA Pregnancy Class D; significant malformations (anencephaly, anophthalmia, cleft palate) were observed in 3 (15%) of 20 infants born to cynomolgus monkeys receiving efavirenz during the first trimester at a dose giving plasma levels comparable to systemic human therapeutic exposure. There are 6 retrospective case reports and 1 prospective case report of neural tube defects in humans with first-trimester exposure *[2, 19-20]*; relative risk unclear.	Use of efavirenz should be avoided in the first trimester. Use after the first trimester can be considered if, after consideration of other alternatives, this is the best choice for a specific woman. If efavirenz is to be continued postpartum, adequate contraception must be assured. Women of childbearing potential must be counseled regarding the teratogenic potential of efavirenz and avoidance of pregnancy while on the drug. Because of the known failure rates even with contraception, alternate antiretroviral regimens should be strongly considered in women of childbearing potential.
Insufficient Data to Recommend Use			
Etravirine	No pharmacokinetic studies in human pregnancy.	No experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use during pregnancy.
Protease Inhibitors (PIs)		Hyperglycemia, new onset or exacerbation of diabetes mellitus, and diabetic ketoacidosis reported with PI use; unclear if pregnancy increases risk. Conflicting data regarding preterm delivery in women receiving PIs (see text).	PIs are recommended for use in combination regimens with 2 NRTI drugs.
Recommended Agents			
Lopinavir/ ritonavir	Pharmacokinetic studies of the new lopinavir/ ritonavir tablet formulation are under way, but data are not yet available.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Well-tolerated, short-term safety demonstrated in Phase I/II studies.	Pharmacokinetic studies of the new tablet formulation are under way but are not yet conclusive as to the optimal dose in pregnancy. Some experts would administer standard dosing (2 tablets twice daily) throughout pregnancy and monitor virologic response and lopinavir drug levels, if available. Other experts, extrapolating from the capsule formulation pharmacokinetic data, would increase the dose of the tablet formulation during the third trimester (from 2 tablets to 3 tablets twice daily), returning to standard dosing postpartum. Once-daily lopinavir/ritonavir dosing is not recommended during pregnancy because there are no data to address whether drug levels are adequate with such administration.

Antiretroviral Drug	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Recommendations for Use in Pregnancy
Alternate Agents			
Atazanavir (recommended to be combined with low-dose ritonavir boosting)	Two of three intensive pharmacokinetic studies of atazanavir with ritonavir boosting during pregnancy suggest that standard dosing results in decreased plasma concentrations compared to nonpregnant adults *[21-23]*. Atazanavir concentrations further reduced ~25% with concomitant tenofovir use *[23]*.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Transplacental passage is low, with cord blood concentration averaging 10%–16% of the maternal delivery atazanavir concentration *[21, 23]*. Theoretical concern re: increased indirect bilirubin levels exacerbating physiologic hyperbilirubinemia in the neonate not observed in clinical trials to date *[21-24]*.	Alternative PI for use in combination regimens in pregnancy. Should give as low-dose ritonavir-boosted regimen, may use once-daily dosing. In treatment-naïve patients unable to tolerate ritonavir, 400 mg once-daily dosing without ritonavir boosting may be considered, although there are no data describing atazanavir concentrations or efficacy under these circumstances. If coadministered with tenofovir, atazanavir must be given with low-dose ritonavir boosting.
Indinavir (combined with low-dose ritonavir boosting)	Two studies including 18 women receiving indinavir 800 mg three times daily showed markedly lower levels during pregnancy compared to postpartum, although suppression of HIV RNA was seen *[25-26]*. In a study of ritonavir-boosted indinavir (400 mg indinavir/100 mg ritonavir twice daily), 82% of women met the target trough level *[27]*.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Theoretical concern re: increased indirect bilirubin levels, which may exacerbate physiologic hyperbilirubinemia in the neonate, but minimal placental passage. Use of unboosted indinavir during pregnancy is not recommended.	Alternate PI for use in combination regimens in pregnancy. Must give as low-dose ritonavir-boosted regimen.
Nelfinavir	Adequate drug levels are achieved in pregnant women with nelfinavir 1,250 mg given twice daily, although levels are variable in late pregnancy *[28-30]*. In a study of pregnant women in their second and third trimester dosed at 1,250 mg given twice daily, women in the third trimester had lower concentration of nelfinavir than women in the second trimester *[30]*. In a study of the new 625-mg tablet formulation dosed at 1,250 mg twice daily, lower AUC and peak levels were observed during the third trimester of pregnancy than postpartum *[31]*.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects) *[2]*. Well-tolerated, short-term safety demonstrated for mother and infant.	Given pharmacokinetic data and extensive experience with use in pregnancy, nelfinavir is an alternative PI for combination regimens in pregnant women receiving combination antiretroviral drugs only for perinatal prophylaxis. In clinical trials of initial therapy in nonpregnant adults, nelfinavir-based regimens had a lower rate of viral response compared to lopinavir-ritonavir or efavirenz-based regimens but similar viral response to atazanavir- or nevirapine-based regimens.

Antiretroviral Drug	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Recommendations for Use in Pregnancy
Alternate Agents (continued)			
Ritonavir	Phase I/II study in pregnancy showed lower levels during pregnancy compared to postpartum *[2, 32]*.	Limited experience at full dose in human pregnancy; has been used as low-dose ritonavir boosting with other PIs.	Given low levels in pregnant women when used alone, recommended for use in combination with second PI as low-dose ritonavir "boost" to increase levels of second PI.
Saquinavir HGC (combined with low-dose ritonavir boosting)	Limited pharmacokinetic data on saquinavir HGC and the new 500-mg tablet formulation suggest that 1,000 mg saquinavir HGC/100 mg ritonavir given twice daily achieves adequate saquinavir drug levels in pregnant women *[33]*.	Well-tolerated, short-term safety demonstrated for mother and infant for saquinavir in combination with low-dose ritonavir.	There are only limited pharmacokinetic data on saquinavir HGC and the new tablet formulation in pregnancy. Ritonavir-boosted saquinavir HGC or saquinavir tablets are alternative PIs for combination regimens in pregnancy and are alternative initial antiretroviral recommendations for nonpregnant adults. Must give as low-dose ritonavir-boosted regimen.
Insufficient Data to Recommend Use			
Darunavir (combined with low-dose ritonavir boosting)	No pharmacokinetic studies in human pregnancy.	No experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use during pregnancy. Must give as low-dose ritonavir-boosted regimen.
Fosamprenavir (recommended to be combined with low-dose ritonavir boosting)	No pharmacokinetic studies in human pregnancy.	Limited experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use during pregnancy. Recommended to be given as low-dose ritonavir-boosted regimen.
Tipranavir (combined with low-dose ritonavir boosting)	No pharmacokinetic studies in human pregnancy.	No experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use during pregnancy. Must give as low-dose ritonavir-boosted regimen.
Entry Inhibitors			
Insufficient Data to Recommend Use			
Enfuvirtide	No pharmacokinetic studies in human pregnancy.	Minimal data in human pregnancy *[34]*.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use during pregnancy.
Maraviroc	No pharmacokinetic studies in human pregnancy.	No experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use during pregnancy.

Antiretroviral Drug	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Recommendations for Use in Pregnancy
Integrase Inhibitors			
Insufficient Data to Recommend Use			
Raltegravir	No pharmacokinetic studies in human pregnancy.	No experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use during pregnancy.

Abbreviations: AUC: area under the curve; HGC: hard gel capsule; NRTI: nucleoside reverse transcriptase inhibitor; NtRTI: nucleotide reverse transcriptase inhibitor; NNRTI: non-nucleoside reverse transcriptase inhibitor; PI: protease inhibitor.

* Zidovudine and lamivudine are included as a fixed-dose combination in Combivir; zidovudine, lamivudine, and abacavir are included as a fixed-dose combination in Trizivir; lamivudine and abacavir are included as a fixed-dose combination in Epzicom.

† Emtricitabine and tenofovir are included as a fixed-dose combination in Truvada; emtricitabine, tenofovir, and efavirenz are included as a fixed-dose combination in Atripla.

\# Triple NRTI regimens including abacavir have been less potent virologically compared to PI-based combination antiretroviral drug regimens. Triple NRTI regimens should be used only when an NNRTI- or PI-based combination regimen cannot be used (e.g., due to significant drug interactions).

Table 6. Clinical Scenario Summary Recommendations for Antiretroviral Drug Use by Pregnant HIV-Infected Women and Prevention of Perinatal Transmission of HIV-1 in the United States

Clinical Scenario	Recommendations
Nonpregnant HIV-infected woman of childbearing potential who has indications for initiating antiretroviral therapy	• Initiate combination antiretroviral drug therapy as per adult treatment guidelines. • Avoid drugs with teratogenic potential (e.g., efavirenz) if the woman is trying to conceive or is not using adequate contraception. Exclude pregnancy before starting treatment with efavirenz.
HIV-infected woman on combination antiretroviral drug therapy who becomes pregnant	**Woman:** • In general, if woman requires treatment, antiretroviral drugs should not be stopped during the first trimester or during pregnancy. • Continue current combination antiretroviral therapy regimen if successfully suppressing viremia; however, avoid use of efavirenz or other potentially teratogenic drugs in the first trimester and drugs with known adverse potential for mother (e.g., combination stavudine/didanosine) throughout the pregnancy. • Perform HIV antiretroviral drug resistance testing if the woman has detectable viremia on therapy. • Continue combination antiretroviral therapy regimen during intrapartum period (zidovudine given as continuous infusion[1] during labor while other antiretroviral agents are continued orally) and postpartum. • Schedule cesarean delivery at 38 weeks gestation if plasma HIV RNA remains >1,000 copies/mL near the time of delivery. **Infant:** • Start zidovudine as soon as possible after birth and administer for 6 weeks.[2]
HIV-infected pregnant woman who is antiretroviral naïve and has indications for antiretroviral therapy	**Woman:** • Perform HIV antiretroviral drug resistance testing prior to initiating combination antiretroviral drug therapy and repeat after initiating therapy if viral suppression is suboptimal. • Initiate combination antiretroviral regimen. - Avoid use of efavirenz or other potentially teratogenic drugs in the first trimester and drugs with known adverse potential for mother (e.g., combination stavudine/didanosine). - Use zidovudine as a component of the antiretroviral regimen when feasible. - Use nevirapine as a component of the antiretroviral regimen only if the woman has CD4 count ≤250 cells/mm^3. If the woman has CD4 count >250 cells/mm^3, use nevirapine as a component of therapy only if the benefit clearly outweighs the risk due to an increased risk of severe hepatic toxicity. • If woman requires immediate initiation of therapy for her own health, initiate treatment as soon as possible, including in the first trimester. • Continue combination antiretroviral therapy regimen during intrapartum period (zidovudine given as continuous infusion[1] during labor while other antiretroviral agents are continued orally) and postpartum. • Schedule cesarean delivery at 38 weeks gestation if plasma HIV RNA remains >1,000 copies/mL near the time of delivery. **Infant:** • Start zidovudine as soon as possible after birth and administer for 6 weeks.[2]

Clinical Scenario	Recommendations
HIV-infected pregnant woman who is antiretroviral naïve and does not require treatment for her own health	**Woman:** • Perform HIV antiretroviral drug resistance testing prior to initiating combination antiretroviral drug therapy and repeat after initiation of therapy if viral suppression is suboptimal. • Prescribe a combination antiretroviral drug prophylaxis regimen (i.e., at least 3 drugs) for prophylaxis of perinatal transmission. - Consider delaying initiation of antiretroviral prophylaxis until after first trimester is completed. - Avoid use of efavirenz or other potentially teratogenic drugs in the first trimester and drugs with known adverse potential for mother (e.g., combination stavudine/didanosine). - Use zidovudine as a component of the antiretroviral regimen when feasible. - If the woman has CD4 count >250 cells/mm^3 use nevirapine as a component of therapy only if the benefit clearly outweighs the risk due to an increased risk of severe hepatic toxicity. • Although use of zidovudine prophylaxis alone is controversial, consider if woman has plasma HIV RNA level <1,000 copies/mL on no therapy. • Continue antiretroviral prophylaxis regimen during intrapartum period (zidovudine given as continuous infusion[1] during labor while other antiretroviral agents are continued orally). • Evaluate need for continuing the combination regimen postpartum; discontinue the combination regimen unless the woman has indications for continued therapy. If regimen includes drug with long half-life like NNRTI, consider stopping NRTIs at least 7 days after stopping NNRTI. (Only limited data exist on this; see **Stopping Antiretroviral Therapy** and **Prevention of Antiretroviral Drug Resistance**.) • Schedule cesarean delivery at 38 weeks gestation if plasma HIV RNA remains >1,000 copies/mL near the time of delivery. **Infant**: • Start zidovudine as soon as possible after birth and administer for 6 weeks.[2]
HIV-infected pregnant woman who is antiretroviral experienced but not currently receiving antiretroviral drugs	**Woman:** • Obtain full antiretroviral treatment history, including prior resistance testing, and evaluate need for antiretroviral treatment for maternal health. • Perform HIV antiretroviral drug resistance testing prior to initiating repeat antiretroviral prophylaxis or therapy and repeat after initiating combination antiretroviral regimen if suboptimal viral suppression. • Initiate a combination antiretroviral regimen (e.g., at least 3 drugs), with regimen chosen based on resistance testing and prior therapy history. - Avoid use of efavirenz or other potentially teratogenic drugs in the first trimester and drugs with known adverse potential for the mother (e.g., combination stavudine/didanosine). - Use zidovudine as a component of the antiretroviral regimen when feasible. - If woman has CD4 count >250 cells/mm^3, use nevirapine as a component of therapy only if the benefit clearly outweighs the risk due to an increased risk of severe hepatic toxicity. • Continue the combination regimen during intrapartum period (zidovudine given as continuous infusion[1] during labor while other antiretroviral agents are continued orally). • Evaluate need for continuing the combination regimen postpartum; discontinue the combination regimen unless the woman has indications for continued therapy. If regimen includes drug with long half-life like NNRTI, consider stopping NRTIs at least 7 days after stopping NNRTI. (Limited data exist on this; see **Stopping Antiretroviral Therapy** and **Prevention of Antiretroviral Drug Resistance**.)

Clinical Scenario	Recommendations
	• Schedule cesarean delivery at 38 weeks gestation if plasma HIV RNA remains >1,000 copies/mL near the time of delivery. **Infant**: • Start zidovudine as soon as possible after birth and administer for 6 weeks.[2]
HIV-infected woman who has received no antiretroviral therapy prior to labor	Zidovudine **Woman:** Give zidovudine as continuous infusion[1] during labor. **Infant:** Start zidovudine as soon as possible after birth and administer for 6 weeks.[2] ***OR*** Combination Zidovudine + Single-dose Nevirapine **Woman:** Give zidovudine as continuous infusion[1] during labor, plus single-dose nevirapine [3] at onset of labor. Consider adding lamivudine during labor and maternal zidovudine/lamivudine for at least 7 days postpartum, which may reduce development of nevirapine resistance. **Infant:** Give single-dose nevirapine[3] plus zidovudine for 6 weeks. ***OR*** **Woman:** Give zidovudine as continuous infusion[1] during labor. **Infant:** Although some clinicians may choose to use zidovudine in combination with additional drugs in the infant, appropriate dosing for neonates is incompletely defined and the additional efficacy of this approach in reducing transmission is not known. Consider consultation with a pediatric HIV specialist. • Evaluate need for initiation of maternal therapy postpartum.
Infant born to HIV-infected woman who has received no antiretroviral therapy prior to or during labor	• Start zidovudine as soon as possible after birth and administer for 6 weeks.[2] ***OR*** • Although some clinicians may choose to use zidovudine in combination with additional drugs, appropriate dosing for neonates is incompletely defined and the additional efficacy of this approach in reducing transmission is not known. Consider consultation with a pediatric HIV specialist. • Evaluate need for initiation of maternal therapy postpartum.

[1] Zidovudine continuous infusion: 2 mg/kg zidovudine intravenously over 1 hour, followed by continuous infusion of 1 mg/kg/hour until delivery.

[2] Zidovudine dosing for infants <35 weeks gestation at birth is 1.5 mg/kg/dose intravenously or 2.0 mg/kg/dose orally, every 12 hours, advancing to every 8 hours at 2 weeks of age if ≥30 weeks gestation at birth or at 4 weeks of age if <30 weeks gestation at birth.

[3] Single-dose nevirapine: Mother: 200 mg given once orally at onset of labor; Infant: 2 mg/kg body weight given once orally at 2–3 days of age if mother received intrapartum single-dose nevirapine or given at birth if mother did not receive intrapartum single-dose nevirapine.

Hepatitis B Virus Coinfection

Panel's Recommendations:

- ***Screening for hepatitis B virus (HBV) infection is recommended for all HIV-infected pregnant women who have not been screened during the current pregnancy (AII).***
- ***Pregnant women who screen negative for hepatitis B should receive the HBV vaccine series (AII).***
- ***Pregnant women with HBV infection should be screened for hepatitis A virus (HAV) and those who screen negative should receive the HAV vaccine series (AII).***
- ***Interferon-alpha and pegylated interferon-alpha are not recommended during pregnancy (AIII).***
- ***Because the optimal management for pregnant and postpartum women with HIV/HBV coinfection is not well defined, consultation with an expert in HIV and HBV is strongly recommended (AIII).***
- ***Decisions about the choice of antiretroviral regimen during pregnancy for HIV/HBV-coinfected women should take into account indications for HIV therapy as determined by maternal CD4 cell count and HIV disease status, HBV levels and indications for HBV therapy, gestational age when starting the antiretroviral regimen, and patient preference (AIII).***
- ***The determination of optimal antepartum antiretroviral regimen for an HIV/HBV-coinfected woman depends on whether she requires anti-HIV treatment for her own health, anti-HBV treatment, both, or neither.***
    - ***For coinfected women with indications for antiretroviral therapy for their own health and who are expected to continue drugs postpartum and/or who require treatment for HBV infection:***
        - ***A three-drug combination antepartum antiretroviral regimen including two agents with anti-HBV activity (e.g., tenofovir plus either lamivudine or emtricitabine) should be used and continued postpartum (BII).***
    - ***For coinfected women who receive antiretroviral drugs during pregnancy solely as prophylaxis for prevention of mother-to-child transmission of HIV, who are expected to discontinue antiretroviral prophylaxis after delivery, and who do not require treatment for HBV infection, the choice is more complex and can include:***
        - ***A three-drug combination antepartum antiretroviral regimen including two NRTI agents with anti-HBV activity (e.g., tenofovir plus either lamivudine or emtricitabine) and stopping prophylaxis after delivery (with monitoring for HBV flare) (BIII); or***
        - ***A three-drug combination antepartum antiretroviral regimen that includes only NRTI agents without anti-HBV activity (e.g., abacavir, didanosine, stavudine, or zidovudine) and stopping prophylaxis after delivery (BIII); or***
        - ***A three-drug combination antepartum antiretroviral regimen including lamivudine as the sole anti-HBV agent could be considered for women presenting late in pregnancy (e.g., after 28 weeks gestation) and stopping prophylaxis after delivery (with monitoring for HBV flare) (CIII).***
- ***Pregnant women with HBV/HIV coinfection receiving antiretroviral drugs should be counseled about signs and symptoms of liver toxicity, and liver transaminases should be assessed 2 weeks following initiation of antiretroviral therapy or prophylaxis and then at least monthly (BIII).***
- ***Infants born to women with hepatitis B infection should receive hepatitis B immune globulin (HBIG) and the first dose of the hepatitis B vaccine series within 12 hours of birth; the second and third doses of vaccine should be administered at 1 and 6 months of age, respectively (AI).***

For additional information on hepatitis B and HIV, see *Hepatitis B Virus Infection* (pages 75–84) in the "Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents, Recommendations from CDC, NIH, and the HIV Medicine Association (HIVMA) of the Infectious Diseases Society of America (IDSA)" at **http://www.cdc.gov/mmwr/pdf/rr/rr5804.pdf** *[1]*.

All HIV-infected pregnant women should be screened for hepatitis A, B, and C. The management of HBV/HIV coinfection in pregnancy is complex and consultation with an expert in HIV and HBV infection is strongly recommended. HIV-infected women who are found to have chronic hepatitis B on the basis of hepatitis B surface antigen for at least 6 months and who are hepatitis A IgG negative should receive the hepatitis A virus (HAV) vaccine series because of the added risk of acute hepatitis A in persons with chronic viral hepatitis.

HIV-infected women who are found to be hepatitis B surface antibody and hepatitis B surface antigen negative should receive the HBV vaccine series. Some patients test positive for anti-HBc alone, which might signify a false-positive result; exposure in the past with subsequent loss of anti-HBs; or "occult" HBV infection, which can be confirmed by detection of HBV DNA *[2-3]*. The clinical significance of isolated anti-HBc is unknown *[4-5]*. Some specialists recommend that HIV-infected persons with anti-HBc alone should be tested for HBV DNA before vaccination for HBV or before initiating antiretroviral drug treatment or prophylaxis because of the risk of reactivation of HBV and the occurrence of immune reconstitution inflammatory syndrome (IRIS) *[1]*. There are limited data regarding the optimal treatment of HIV-infected pregnant women with chronic HBV coinfection (i.e., hepatitis B surface antigen positive for >6 months). There are no definitive studies on the safety of antiviral therapy for hepatitis B infection during pregnancy and breastfeeding; interferon and peg-interferon are not recommended during pregnancy.

Current treatment guidelines for HBV/HIV-coinfected nonpregnant adults who require treatment of their HIV infection recommend the NRTI combination of tenofovir plus emtricitabine or tenofovir plus lamivudine as the dual NRTI backbone of an antiretroviral regimen, regardless of the need for concomitant HBV treatment *[6]*.Tenofovir, lamivudine, and emtricitabine all show activity against HBV. Because of the risk of development of HBV-resistant mutants, use of two agents active against HBV (tenofovir plus lamivudine or emtricitabine) is recommended as the dual NRTI backbone when antiretroviral treatment is required.

Lamivudine is a recommended NRTI and emtricitabine is an alternative NRTI for use in pregnancy. There are only limited data on the use of tenofovir during pregnancy. Tenofovir is not teratogenic in animals but reversible bone changes at high doses were seen in multiple animal species. Although tenofovir is not generally recommended in pregnancy as a first-line agent for antiretroviral regimens being used solely for prophylaxis of mother-to-child transmission of HIV, HBV/HIV coinfection in pregnancy may be a special circumstance where tenofovir may be more strongly considered (see **Table 5**). For pregnant women with HBV/HIV coinfection who require treatment of HIV disease for their own health or who require treatment of chronic HBV disease, the benefit of tenofovir outweighs potential risks, and tenofovir plus lamivudine or emtricitabine is recommended as the dual NRTI backbone of a three-drug therapeutic regimen. Although zidovudine should generally be a component of antiretroviral regimens in pregnancy, in HBV/HIV-coinfected women this may not be feasible.

A three-drug regimen including tenofovir plus lamivudine or emtricitabine is also recommended for HBV/HIV-coinfected pregnant women who do not require treatment of HIV but who do require treatment of their HBV disease. In nonpregnant coinfected patients who require treatment of HBV disease but not of HIV, pegylated interferon-alpha treatment is recommended. However, this drug is not recommended in pregnancy. Additionally, the use of tenofovir plus lamivudine or emtricitabine without a third antiretroviral drug should be avoided because of the rapid development of drug-resistant HIV mutations. Entecavir should not be used for treatment of HBV infection without concomitant combination treatment for HIV infection because recent data suggest that the M184V resistance mutation may emerge in HIV-infected patients receiving entecavir alone *[7]*. Entecavir is associated with skeletal anomalies in rats and rabbits but only at high, maternally toxic doses. Data on use of entecavir in human pregnancy are not available. Postpartum, the patient could stop the antiretroviral regimen and initiate HBV-specific therapy (e.g., pegylated interferon-alpha) to continue HBV treatment or continue the three-drug antiretroviral regimen.

There is controversy regarding the appropriate approach to therapy for pregnant women with HBV/HIV coinfection who do not require treatment of HIV or HBV disease, and therefore are receiving antiretroviral drugs solely for prevention of perinatal transmission of HIV and will discontinue therapy postpartum. Although there are only limited data about the safety of tenofovir in pregnancy, some experts recommend use of a three-drug regimen that includes the anti-HBV drug tenofovir plus lamivudine or emtricitabine as the dual NRTI backbone due to concern about HBV immune reconstitution inflammatory syndrome (IRIS) with initiation of therapy. Although concern about antiretroviral treatment-induced HBV IRIS should be less in this group of pregnant women because they do not require therapy for their own health and therefore do not have severe immunodeficiency (the greatest risk factor for development of IRIS following initiation of antiretroviral therapy), treating a potential HBV flare in the postpartum period after discontinuing HBV-active therapy may be associated with less risk than treating an immune-mediated flare during pregnancy. In addition, using drugs with anti-HBV activity during pregnancy will lower HBV levels and potentially decrease the risk of failure of hepatitis B immune globulin (HBIG) and hepatitis B vaccine to prevent perinatal transmission of HBV, which is increased among women with very high HBV DNA levels. If such an approach is followed, liver function should be carefully monitored postpartum following discontinuation of drugs; if severe flare-up of HBV disease occurs postpartum, initiation of anti-HBV-specific therapy such as pegylated interferon-alpha can be considered.

Alternatively, for women who require prophylaxis of perinatal HIV infection but do not require treatment for HBV infection, some experts choose to use an antiretroviral regimen without anti-HBV activity (e.g., use of a dual NRTI backbone that contains drugs other than tenofovir, lamivudine, or emtricitabine, such as zidovudine and didanosine, could be considered) to avoid the possibility of an HBV flare when treatment is discontinued postpartum. Another alternative used by some specialists for women who require prophylaxis of perinatal HIV infection but do not require treatment of HBV infection is a highly active antiretroviral regimen that includes lamivudine as the only antiretroviral agent with activity against HBV, especially if the regimen is started later in pregnancy because of late care or delayed HIV diagnosis. This option avoids the use of tenofovir during pregnancy because there are only limited data on safety, while still treating HBV; the risk of HBV development of resistance to lamivudine with short-term temporary exposure of less than 6 months is extremely low *[8]*.

An elevation in hepatic enzymes following initiation of antiretroviral therapy may occur in HBV/HIV-coinfected women due to an immune-mediated flare in HBV disease secondary to immune reconstitution with therapy, particularly in women with low CD4+ cell count at the time of initiation of therapy. HBV infection may also increase hepatotoxic risk of certain antiretroviral agents, specifically protease inhibitors and nevirapine. Pregnant women with HBV/HIV coinfection should be counseled about signs and symptoms of liver toxicity, and transaminases should be assessed 2 weeks following initiation of antiretroviral therapy or prophylaxis in women not already receiving drugs and then at least monthly. If hepatic toxicity occurs, substitution of a less hepatotoxic drug regimen may need to be considered or, if clinical symptoms or significant elevations of transaminases occur, drugs may need to be temporarily discontinued. It can be difficult to differentiate a flare in HBV disease due to immune reconstitution from drug toxicity, and consultation with an expert in HIV infection is recommended.

All infants born to HBV surface antigen positive mothers should receive hepatitis B immune globulin (HBIG) and the first dose of the hepatitis B vaccination series within 12 hours of birth. The second and third doses of vaccine should be administered at 1 and 6 months of age, respectively. This regimen is >95% effective in preventing HBV infection in these infants.

Hepatitis C Virus Coinfection

Panel's Recommendations:

- ***Screening for hepatitis C virus (HCV) infection is recommended for all HIV-infected pregnant women who have not been screened during the current pregnancy (AIII).***
- ***Pegylated interferon-alpha is not recommended and ribavirin is contraindicated during pregnancy (AII).***
- ***Recommendations for antiretroviral drug use during pregnancy are the same for women who are coinfected with HCV as for those without HCV coinfection (BIII).***
- ***Pregnant women with HCV/HIV coinfection receiving antiretroviral drugs should be counseled about signs and symptoms of liver toxicity, and transaminases should be assessed 2 weeks following initiation of antiretroviral therapy or prophylaxis in women not already receiving drugs and then at least monthly (BIII).***
- ***Decisions concerning mode of delivery in HCV/HIV-coinfected pregnant women should be based on considerations related to HIV infection alone (see Intrapartum Care) (BIII).***
- ***Infants born to women with HCV/HIV coinfection should be evaluated for HCV infection (AIII) by HCV RNA testing between 2 and 6 months of age and/or HCV antibody testing after 15 months of age (CIII).***
- ***Because of the added risk of acute hepatitis A and B in persons with chronic viral hepatitis C, women who are found to have chronic HCV infection should be screened for hepatitis A and hepatitis B infections. If women with chronic hepatitis C are hepatitis A IgG negative, they should receive the hepatitis A virus (HAV) vaccine series, and if they are hepatitis B uninfected (e.g., hepatitis B surface Ag negative, hepatitis B core antibody negative, and hepatitis B surface antibody negative), they should receive the HBV vaccine series (AIII).***

For additional information on hepatitis C and HIV, see *Hepatitis C Virus Infection* (pages 84–91) of the "Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-infected Adults and Adolescents, Recommendations from CDC, NIH, and the HIV Medicine Association (HIVMA) of the Infectious Diseases Society of America (IDSA)" at **http://www.cdc.gov/mmwr/pdf/rr/rr5804.pdf** *[1]*.

HCV/HIV coinfection is not uncommon in HIV-infected women, particularly among women infected via parenteral drug use; among HIV-infected pregnant women, the HCV seroprevalence rate ranges from 17%–54% *[2]*. Screening for HCV infection using a sensitive immunoassay for HCV antibody is recommended for all HIV-infected individuals, including pregnant women. False-negative anti-HCV immunoassay results may occur among HIV-infected persons, particularly those with very low CD4 counts, but this is uncommon with the most sensitive immunoassays. If serologic test results are indeterminate or HCV infection is suspected due to elevated aminotransaminases or risk factors such as a history of intravenous drug use, testing for HCV RNA should be performed.

There are few data on the optimal management of HIV-infected pregnant women with HCV coinfection. There are no definitive studies on the safety of HCV antiviral therapy during pregnancy. Interferon and peg-interferon are not recommended for use in pregnancy, and ribavirin is contraindicated in pregnancy. Although interferons are not teratogenic, they are abortifacient at high doses in monkeys and should not be used in pregnant women because of the direct antigrowth and antiproliferative effects of these agents *[3]*. Ribavirin is labeled as FDA pregnancy category X because of its teratogenicity at low doses in multiple animal species; defects noted in animals include limb abnormalities, craniofacial defects, anencephaly, and anophthalmia. Pregnancy does not appear to influence the course of HCV infection and women with chronic viral hepatitis generally do quite well during pregnancy, providing that they have not progressed to decompensated cirrhosis *[4]*.

Because of the added risk of acute hepatitis A and B in persons with chronic viral hepatitis C, women who are found to have chronic HCV infection should be screened for hepatitis A and hepatitis B infections. If women with chronic HCV infection are hepatitis A IgG negative, they should receive the HAV vaccine series, and if they are hepatitis B uninfected (e.g., hepatitis B surface Ag negative, hepatitis B core antibody negative, and hepatitis B surface antibody negative), they should receive the HBV vaccine series.

Coinfection with HIV has been shown to increase significantly the risk of perinatal transmission of HCV, likely related to increase in HCV viremia and/or other HIV-related impact on HCV disease activity *[5]*. A European study of perinatal transmission of HCV found that use of effective combination antiretroviral therapy was associated with a strong trend for reduction in HCV transmission (OR 0.26, 95% CI, 0.07–1.01) *[6]*. However, although the median HCV viral load was lower among women treated with combination antiretroviral regimens compared to women on a single drug or receiving no treatment (656,101 copies/mL vs. 850,000 copies/mL, respectively), this difference was neither statistically nor clinically significant. Maternal HCV/HIV coinfection may also increase the risk of perinatal transmission of HIV *[7]*. Therefore, potent combination antiretroviral therapy with three drugs should be considered for all HCV/HIV-coinfected pregnant women, regardless of CD4 count or HIV viral load, with discontinuation of therapy postpartum in women who do not require therapy for their own health.

Similar to HBV infection, an elevation in hepatic enzymes following initiation of antiretroviral therapy may occur in HCV/HIV-coinfected women. This elevation in hepatic enzymes may be due to an immune-mediated flare in HCV disease secondary to immune reconstitution with therapy, particularly in women with low CD4 cell count at the time of initiation of therapy. Like HBV, HCV infection may increase hepatotoxic risk of certain antiretroviral agents, specifically protease inhibitors and nevirapine. Pregnant women with HCV/HIV coinfection should be counseled about signs and symptoms of liver toxicity, and transaminases should be assessed 2 weeks following initiation of antiretroviral therapy or prophylaxis in women not already receiving drugs and then at least monthly. If hepatic toxicity occurs, substitution of a less hepatotoxic drug regimen may need to be considered or, if clinical symptoms or significant elevations of transaminases occur, drugs may need to be temporarily discontinued. It can be difficult to differentiate a flare in HCV disease due to immune reconstitution from drug toxicity, and consultation with an expert in HIV infection is recommended.

Similar to HIV transmission, internal fetal monitoring and duration of membrane rupture greater than 6 hours may increase risk of HCV transmission; general recommendations for intrapartum management are unchanged from those for women with HIV infection alone (see **Intrapartum Care**). Data are inconclusive regarding the role of scheduled cesarean delivery in reducing the risk of HCV transmission in the setting of HIV infection. Currently, there is no evidence from randomized controlled trials upon which to base any practice recommendations regarding scheduled cesarean delivery versus vaginal delivery for preventing mother-to-infant transmission of HCV *[8]*. In two observational studies from the European Hepatitis C Virus Network, the first study reported that scheduled cesarean delivery was protective against HCV transmission in HIV-coinfected women, but the second study found no benefit to scheduled cesarean delivery, possibly related to the increased use of combination antiretroviral drug regimens in the second report *[9]*. At the current time, decisions concerning mode of delivery in HCV/HIV-coinfected pregnant women should be based on HIV considerations alone (see **Intrapartum Care**).

Infants born to women with HCV/HIV coinfection should be assessed for HCV infection by HCV RNA virologic testing between 2 and 6 months of age (at least two negative tests are needed to exclude HCV infection because HCV viremia can be intermittent) and/or testing for anti-HCV antibody after age 15 months *[10]*.

Stopping Antiretroviral Therapy during Pregnancy

Panel's Recommendations:

- ***If an antiretroviral drug regimen is stopped acutely for severe or life-threatening toxicity or severe pregnancy-induced hyperemesis unresponsive to anti-emetics, all drugs should be stopped at the same time and reinitiated at the same time (AIII).***
- ***If an antiretroviral drug regimen is stopped electively and the patient is receiving an NNRTI drug, consideration should be given to either (1) stopping the NNRTI first and continuing the other antiretroviral drugs for a period of time or (2) switching from an NNRTI to a PI prior to interruption and continuing the PI with the other antiretroviral drugs for a period of time before electively stopping. The optimal interval between stopping an NNRTI and the other antiretroviral drugs is not known; at least 7 days is recommended. Given the potential for prolonged detectable NNRTI concentrations for more than 3 weeks in patients receiving efavirenz-based therapy, some experts recommend continuing the other antiretroviral agents or substituting a PI plus two other agents for up to 30 days (CIII).***
- ***If nevirapine is stopped and more than 2 weeks have passed prior to restarting therapy, nevirapine should be restarted with the 2-week dose escalation period (AII).***

Discontinuation of antiretroviral drug regimens during pregnancy may be indicated in some situations including serious drug-related toxicity, pregnancy-induced hyperemesis, acute illnesses or planned surgeries that preclude oral intake, lack of available medication, or patient request.

Continuation of all drugs during the intrapartum period is generally recommended. Women who are having an elective cesarean section can take oral medications prior to the scheduled surgery and restart drugs following

surgery. Given that most drugs are given once or twice daily, the woman would either not miss any doses or at most receive the postpartum dose a few hours late.

When short-term drug interruption is indicated, in most cases, all antiretroviral drugs should be stopped and reintroduced at the same time. This can be problematic with drugs that have a long half-life. However, in conditions such as severe or life-threatening toxicity or severe pregnancy-induced hyperemesis unresponsive to anti-emetics, the clinician has no choice but to stop all therapy at the same time.

NNRTI drugs like nevirapine and efavirenz have very long half-lives and can be detected for 21 days or longer after discontinuation; efavirenz has a longer half-life than nevirapine *[1-5]*. As the other drugs with shorter half-lives are cleared, only the NNRTI drug may persist, resulting in persistent subtherapeutic drug levels that can increase the risk of selection of NNRTI-resistant mutations. In addition, it is known that certain genetic polymorphisms may result in slower rate of clearance. These polymorphisms may be more common among some ethnic groups, such as in African Americans and in Hispanics *[3, 5]*. To prevent prolonged exposure to a single drug, some experts recommend stopping the NNRTI first and continuing the other antiretroviral drugs for a period of time *[2]*. However, the optimal interval between stopping an NNRTI and the other antiretroviral drugs is not known; detectable levels of NNRTIs may be present from less than 1 week to greater than 3 weeks after discontinuation (the longer duration is primarily observed with efavirenz) *[5]*. An alternative strategy is to substitute a PI for the NNRTI and to continue the PI with dual NRTIs for a period of time. In a post-study analysis of the patients who interrupted therapy in the SMART trial, patients who were switched from an NNRTI to a PI-based regimen prior to interruption had a lower rate of NNRTI-resistant mutation after interruption and a greater chance of resuppression of HIV-RNA after restarting therapy than those who stopped all the drugs simultaneously or stopped the NNRTI before the dual-NRTIs *[6]*. The optimal duration needed to continue either dual nucleosides or the substituted PI-based regimen after stopping the NNRTI is not known; at least 7 days is recommended based on studies to reduce resistance following single-dose nevirapine *[7]*. With efavirenz use, there is the potential of prolonged detectable NNRTI concentrations for more than 3 weeks; therefore some suggest if stopping efavirenz-based therapy, the dual nucleosides or PI may need to be continued for up to 30 days. Further research is needed to assess appropriate strategies for stopping NNRTI-containing combination regimens.

An additional consideration is reintroduction of nevirapine if it is temporarily stopped for some reason and subsequently restarted. Currently, a 2-week, half-dose escalation is recommended in patients who are started on nevirapine. Dose escalation is necessary because nevirapine induces its own metabolism by inducing CYP3A4 liver metabolic enzymes; thus, initial administration of the full therapeutic dose will result in elevated drug levels until metabolic enzyme induction has occurred. In cases where nevirapine has been discontinued for more than 2 weeks, it is recommended that another 2-week dose escalation be used when it is reintroduced.

Failure of Viral Suppression

Panel's Recommendations:

- ***If there is failure of viral suppression after an adequate period of treatment:***
  - ***Assess resistance and adherence (AII).***
  - ***Consult an expert in the care of HIV-infected adults (AIII).***
- ***Scheduled cesarean delivery is recommended for HIV-infected pregnant women who have HIV RNA levels >1,000 copies/mL near the time of delivery (AII).***

The management of women on chronic antiretroviral therapy who have suboptimal suppression of HIV RNA (i.e., detectable virus at any time during pregnancy) should include evaluation for resistant virus, assessment of adherence, incorrect dosing or potential problems with absorption (e.g., with nausea/vomiting or lack of attention to food requirements), and consideration of modification of antiretroviral therapy. Experts in the care

of antiretroviral-experienced adults should be consulted, in particular when a change in drug regimen is necessary.

HIV RNA levels should be assessed 2 to 6 weeks following initiation or change of antiretroviral drug regimen to provide an initial assessment of efficacy *[8]*. Baseline HIV RNA levels have been shown to affect the time course of response in pregnant as well as nonpregnant individuals *[9]*. Most patients with an adequate viral response at 24 weeks have had at least a 1 $\log_{10}$ copies/mL HIV RNA decrease by 1 to 4 weeks after starting therapy *[8]*. Treatment-naïve individuals should have HIV RNA <400 copies/mL after 24 weeks of treatment and <50 copies/mL after 48 weeks of treatment.

Because maternal antenatal viral load correlates with risk of perinatal HIV transmission, suppression of HIV RNA to undetectable levels should be achieved as rapidly as possible. Scheduled cesarean delivery is recommended for HIV-infected pregnant women who have HIV RNA levels >1,000 copies/mL near the time of delivery (see **Transmission and Mode of Delivery**).

MONITORING OF THE WOMAN AND FETUS DURING PREGNANCY

Panel's Recommendations:

- ***CD4 cell count should be monitored at the initial antenatal visit (AI) and at least every 3 months during pregnancy (BIII).***
- ***Plasma HIV RNA levels should be monitored at the initial visit (AI); 2 to 4 weeks after initiating (or changing) antiretroviral therapy (BI); monthly until RNA levels are undetectable (BII); and then at least every 3 months during pregnancy (BIII). HIV RNA levels should also be assessed at approximately 34 to 36 weeks gestation to inform decisions on mode of delivery (see Transmission and Mode of Delivery) (AIII).***
- ***Antiretroviral drug resistance testing should be performed in all pregnant women prior to initiating antiretroviral treatment or prophylaxis, in pregnant women who have suboptimal viral suppression after initiation of antiretroviral drugs (failure to achieve a 1 log_{10} copies/mL drop in HIV RNA at 30 days or lack of progressive decline to undetectable HIV RNA levels by 16 to 24 weeks of therapy), and in pregnant women who have persistently detectable plasma HIV RNA levels after treatment previously suppressed the virus to lower than the assay level of detection (AII).***
- ***Monitoring for complications of antiretroviral drugs during pregnancy should be based on what is known about side effects of the drugs the woman is receiving (AIII).***
- ***First-trimester ultrasound is recommended for confirmation of gestational age and potential timing for scheduled cesarean delivery, if needed (see Transmission and Mode of Delivery) (AII).***
- ***Given the limited data on the effect of combination therapy on the fetus, most experts would recommend second-trimester ultrasound to assess fetal anatomy for women who have received combination antiretroviral therapy (particularly if the regimen included efavirenz) during the first trimester (BIII).***
- ***Among women on combination antiretroviral drug regimens, no perinatal transmissions have been reported after amniocentesis, but a small risk of transmission cannot be ruled out. If amniocentesis is indicated in HIV-infected women, it should be done only after initiation of combination antiretroviral drug therapy or prophylaxis and ideally when HIV RNA levels are undetectable (BIII).***

CD4 cell count should be monitored in HIV-infected pregnant women at the initial visit and at least every 3 months during pregnancy, similar to recommendations in nonpregnant adults. Viral load should be monitored in HIV-infected pregnant women at the initial visit, 2 to 4 weeks after initiating or changing antiretroviral therapy, monthly until undetectable, and then at least every 3 months. If there is concern regarding adherence, more frequent monitoring is recommended because of the potential increased risk of perinatal HIV infection if there is detectable HIV viremia during pregnancy. More frequent monitoring of viral load is recommended in pregnant versus nonpregnant individuals because of the urgency to lower viral load as rapidly as possible to reduce perinatal transmission risk. Therefore, there is a need to identify pregnant women whose decline in viral load is slower than expected. Adult antiretroviral guidelines note that patients should have a decrease in plasma HIV RNA level by at least one log_{10} copies/mL by 1 month after initiation of potent therapy (Adult guidelines). Generally, most treatment-adherent individuals not harboring resistance mutations to the drugs they are receiving achieve viral suppression in 16 to 24 weeks, although rarely it may take longer for some patients. Viral load should also be assessed at approximately 34 to 36 weeks gestation to inform decisions on mode of delivery (see **Transmission and Mode of Delivery**).

Due to physiologic changes such as hemodilution during pregnancy, CD4 percentage may be more stable than absolute CD4 count during pregnancy *[1-2]*. However, because parameters for initiating therapy are based primarily on absolute CD4 count, most clinicians still rely on CD4 count to evaluate immune status during pregnancy.

Antiretroviral drug resistance testing should be performed in pregnant women prior to initiating antiretroviral treatment or prophylaxis and in those women who have suboptimal viral suppression after initiation of antiretroviral drugs or who have persistently detectable plasma HIV RNA levels after treatment previously suppressed the virus to lower than the assay level of detection (see **Antiretroviral Drug Resistance and Resistance Testing in Pregnancy**). Drug resistance testing in the setting of viral failure should be performed while the patient is receiving antiretroviral drugs or immediately (i.e., up to 4 weeks) after discontinuing therapy.

Monitoring for potential complications of antiretroviral drugs during pregnancy should be based on what is known about the side effects of the drugs the woman is receiving. For example, routine hematologic monitoring is recommended for women receiving zidovudine-containing regimens. Liver function should be monitored in all women receiving antiretroviral drugs. Hepatic dysfunction has been observed in pregnant women on protease inhibitors, and hepatic steatosis and lactic acidosis in pregnancy has been related to NRTI use. Women, particularly those with CD4 counts >250 cells/mm^3, have an increased risk of developing symptomatic, rash-associated, nevirapine-associated hepatotoxicity within the first 18 weeks after initiation of therapy. Pregnant women initiating therapy with nevirapine should have more frequent and careful monitoring of transaminase levels (see **Nevirapine and Hepatic/Rash Toxicity**).

First-trimester ultrasound is recommended for confirmation of gestational age and, if needed, to guide potential timing of scheduled cesarean delivery because scheduled cesarean deliveries for prevention of perinatal HIV transmission should be performed at 38 weeks gestation (see **Transmission and Mode of Delivery**). Research studies show that first-trimester ultrasound, which is currently recommended by the American Congress of Obstetricians and Gynecologists is the most accurate procedure for dating of pregnancy *[3-4]*. If the patient is not seen until later in gestation, then second-trimester ultrasound can be used for both anatomy scanning and determining gestational age.

Because less is known about the effect of combination antiretroviral therapy on the fetus during pregnancy, some experts consider more intensive fetal assessment for mothers receiving such therapy. Most experts would recommend second-trimester assessment of fetal anatomy with ultrasound in women who have received combination antiretroviral therapy during the first trimester, particularly if the regimen included efavirenz. Furthermore, in addition to standard clinical monitoring, some experts would also recommend ultrasound assessment of fetal growth and well-being during the third trimester if the woman was receiving a combination drug regimen for which there is limited experience with use in pregnancy. The need for additional assessments such as non-stress testing should be determined based on ultrasound findings and any maternal comorbidities.

In the pre-HAART era, invasive procedures such as amniocentesis and chorionic villus sampling were associated with a two- to four-fold increased risk of vertical transmission of HIV *[5-7]*. Data from the HAART era are still limited but do not suggest an increased risk of transmission for women receiving combination antiretroviral drug regimens before amniocentesis or other invasive diagnostic procedure. In an evaluation of transmission rates over time among women with or without amniocentesis, the transmission rate among women undergoing the procedure from 1984 to 1996 (pre-HAART) was 3 (30%) of 10 compared to 40 (16.2%) of 247 among women without amniocentesis (NS) *[8]*. No transmissions were noted among 18 women undergoing amniocentesis between 1997 and 2000 and receiving antiretroviral drug regimens *[8]*. In a multi-center study from Italy including deliveries between 1997 and 2003, 2 (3.3%) of 60 infants were HIV infected after early invasive diagnostic procedures (chorionic villus sampling, amniocentesis, or cordocentesis) during pregnancy compared to 1.7% of 712 infants born to women without invasive procedures (p = 0.30) *[9]*. No transmissions occurred among 45 women on combination antiretroviral drug regimens during the

procedure. One mother of an infected infant had not been diagnosed as HIV infected at the time of amniocentesis so was not receiving antiretroviral prophylaxis; the newborn's virologic test at birth was negative. The mother of a second infected infant had been receiving zidovudine prophylaxis for 3 weeks and had an HIV RNA level of 10,000 copies/mL at the time of the procedure; the preterm infant had a positive virologic test at birth. In 2 other single-center series, no transmissions occurred in the 6 and 9 liveborns after amniocentesis among HIV-infected pregnant women on combination antiretroviral drug regimens *[10-11]*. In the largest series to date, no transmissions were seen among 81 women receiving combination antiretroviral drug regimens at the time of amniocentesis *[12]*. Thus among 159 cases reported to date of amniocentesis or other invasive diagnostic procedures among women on combination antiretroviral drug regimens, no transmissions have occurred but a small increase in risk cannot be ruled out. HIV-infected women who have indications for invasive testing in pregnancy, such as abnormal ultrasound or serum marker screening, should be counseled about the potential risk of HIV transmission along with other risks of the procedure and allowed to make an informed decision about testing. Some experts consider chorionic villus sampling and cordocentesis too risky to offer to HIV-infected women and recommend limiting procedures to amniocentesis *[10]*. Women should be on a combination antiretroviral drug regimen (e.g., at least 3 drugs), ideally with an undetectable HIV RNA level, before any procedure. Any procedure should be done under continuous ultrasound guidance, and the placenta should not be traversed during amniocentesis.

SPECIAL CONSIDERATIONS REGARDING THE USE OF ANTIRETROVIRAL DRUGS BY HIV-INFECTED PREGNANT WOMEN AND THEIR INFANTS

Panel's Recommendations:

- ***All cases of antiretroviral drug exposure during pregnancy should be reported to the Antiretroviral Pregnancy Registry (see details at http://www.APRegistry.com) (AIII).***
- ***Some protease inhibitors (e.g., lopinavir/ritonavir) may require altered dosing during pregnancy (see Table 5) (AIII).***
- ***Efavirenz is an FDA Pregnancy Category D drug because of animal data showing an increased risk of central nervous system (CNS) defects and a small number of concerning case reports in humans. Efavirenz should not be used in the first trimester of pregnancy and women on efavirenz should be counseled to avoid pregnancy (AIII).***
- ***Although currently published data are conflicting, clinicians should be aware of a possible small increased risk of preterm birth in pregnant women receiving protease inhibitor-based combination antiretroviral therapy or prophylaxis; however, given the clear benefits of such therapy for both the woman's health and the prevention of mother-to-child transmission, protease inhibitors should not be withheld for fear of altering pregnancy outcome (AIII).***
- ***Women with CD4 counts >250 cells/mm^3 initiating nevirapine-containing regimens have an increased risk of developing symptomatic, often rash-associated, nevirapine-related hepatotoxicity that can be severe, life-threatening, and in some cases fatal. Pregnancy does not seem to modify this risk. Therefore, nevirapine should only be used in this setting if the benefits clearly outweigh the risks (AII). However, nevirapine-related toxicity has not been observed with use of single-dose nevirapine for prevention of mother-to-child transmission of HIV.***
- ***HIV-infected women receiving antiretroviral therapy during pregnancy should receive glucose screening with a standard, 1-hour, 50-gram glucose loading test at 24 to 28 weeks gestation (AIII). Some experts would perform earlier glucose screening in women with ongoing chronic protease inhibitor-based therapy initiated prior to pregnancy, similar to recommendations for women with high-risk factors for glucose intolerance (BIII).***

Recommendations regarding the choice of antiretroviral drugs for treatment of HIV-infected pregnant women are subject to unique considerations. These include:

a. possible changes in dosing requirements resulting from physiologic changes associated with pregnancy;

b. potential toxicities of antiretroviral drugs that may be magnified in the pregnant woman;

c. the potential short- and long-term effects of the antiretroviral drug on the fetus and newborn, including the potential for preterm birth, teratogenicity, mutagenicity, or carcinogenicity, which may not be known for certain antiretroviral drugs; and

d. the pharmacokinetics and toxicity of transplacentally transferred drugs.

Treatment recommendations for pregnant women infected with HIV have been based on the concept that therapies of known benefit to women should not be withheld during pregnancy unless there are known adverse effects on the mother, fetus, or infant and unless these adverse effects outweigh the benefit to the woman *[1]*. Pregnancy should not preclude the use of optimal therapeutic regimens. The decision to use any antiretroviral drug during pregnancy should be made by the woman after

discussing with her health care provider the known and potential benefits and risks to her and her fetus.

Although clinical data on antiretroviral drugs in pregnant women are more limited than in nonpregnant individuals, there are sufficient data on some of the available antiretroviral drugs to be able to provide recommendations related to drug choice. **Table 5** provides information on pharmacokinetics in pregnancy and pregnancy-related concerns for each of the available antiretroviral drugs; drugs are classified for use in pregnancy as recommended, alternative, insufficient information, or not recommended. This table should be used in conjunction with the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*** when developing treatment regimens for pregnant women.

Pharmacokinetic Changes

Physiologic changes that occur during pregnancy may affect the kinetics of drug absorption, distribution, biotransformation, and elimination, thereby also affecting requirements for drug dosing and potentially altering the susceptibility of the pregnant woman to drug toxicity *[2-3]*. During pregnancy, gastrointestinal transit time becomes prolonged; body water and fat increase throughout gestation and are accompanied by increases in cardiac output, ventilation, and liver and renal blood flow; plasma protein concentrations decrease; renal sodium reabsorption increases; and changes occur in metabolic enzyme pathways in the liver. Placental transport of drugs, compartmentalization of drugs in the embryo/fetus and placenta, biotransformation of drugs by the fetus and placenta, and elimination of drugs by the fetus also can affect drug pharmacokinetics in the pregnant woman.

Currently available data on the pharmacokinetics of antiretrovirals in pregnancy are summarized in **Table 5**. In general, the pharmacokinetics of NRTI and NNRTI drugs are similar in pregnant and nonpregnant women, although protease inhibitor (e.g., lopinavir/ritonavir) pharmacokinetics are more variable, particularly in later pregnancy.

Teratogenicity

The potential harm to the fetus from maternal ingestion of a specific drug depends not only on the drug itself but also on the dose ingested; the gestational age of the fetus at exposure; the duration of exposure; the interaction with other agents to which the fetus is exposed; and, to an unknown extent, the genetic makeup of the mother and fetus.

Information regarding the safety of drugs in pregnancy is derived from animal toxicity data, anecdotal experience, registry data, and clinical trials. Data are limited for antiretroviral drugs, particularly when used in combination therapy. Drug choice should be individualized and must be based on discussion with the woman and available data from preclinical and clinical testing of the individual drugs. Preclinical data include results of *in vitro* and animal *in vivo* screening tests for carcinogenicity, clastogenicity/mutagenicity, and reproductive and teratogenic effects. However, the predictive value of such tests for adverse effects in humans is unknown. For example, of approximately 1,200 known animal teratogens, only about 30 are known to be teratogenic in humans *[4]*. Limited data exist regarding placental passage, long-term animal carcinogenicity, and animal teratogenicity for the FDA-approved antiretroviral drugs (**Table 4**).

Human data on teratogenicity of FDA-approved antiretrovirals are summarized in **Table 5**. Concerns have been raised about the risk of several of the antiretroviral agents. In cynomolgus monkeys treated with efavirenz from gestational days 20 to 150 at a dose resulting in plasma concentrations comparable to systemic human therapeutic exposure, significant malformations were observed in 3 of 20 infant monkeys *[5]*. The malformations included anencephaly and unilateral anophthalmia in 1;

microphthalmia in another; and cleft palate in the third. In prospectively reported pregnancies with exposure to efavirenz-based regimens in the Antiretroviral Pregnancy Registry through July 2009, birth defects were observed in 14 (2.8%) of 501 live births with first-trimester exposure; this proportion is not significantly different from that observed among U.S. births in the general population (2.7%) as reported by the Registry *[6]*. Defects reported prospectively included 1 report of myelomeningocele and a separate report of anophthalmia. The case of anophthalmia included severe oblique facial clefts and amniotic banding that is known to be associated with anophthalmia *[6]*. In addition, there have been 5 retrospectively detected cases of central nervous system defects, including myelomeningocele, in infants born to mothers receiving efavirenz during the first trimester *[5]*.

Although a causal relationship of these events to the use of efavirenz has not been established, in light of similar findings in primates, efavirenz is classified as FDA Pregnancy Category D and may cause fetal harm when administered to a pregnant woman during the first trimester. Because of the potential for teratogenicity, pregnancy should be avoided in women receiving efavirenz, and treatment with efavirenz should be avoided during the first trimester, which is the primary period of fetal organogenesis. Women of childbearing potential should undergo pregnancy testing prior to initiation of efavirenz and should be counseled about the potential risk to the fetus and need to avoid pregnancy. Alternate antiretroviral regimens that do not include efavirenz should be strongly considered in women who are planning to become pregnant or who are sexually active and not using effective contraception. Use after the first trimester can be considered if, after consideration of other alternatives, this is the best choice for an individual woman. If efavirenz is to be continued postpartum, adequate contraception must be assured (**Table 5**).

Zalcitabine has been associated with an increased risk of hydrocephalus at very high doses in rodents and delavirdine has been associated with an increased risk of ventricular septal defects in rodents. Neither drug is currently available for use in the United States.

Tenofovir has not demonstrated teratogenicity in rodents or monkeys. At doses resulting in levels approximately 25 times those used in humans, low birth weights and reductions in fetal bone porosity were seen. Chronic administration of tenofovir to immature animals of multiple species has resulted in reversible bone abnormalities; these effects were dose, exposure, age, and species specific. Data from the Antiretroviral Pregnancy Registry show a birth defect incidence of 2.4% in 756 women with first-trimester tenofovir exposure, similar to that in the general population *[6]*. However, because of the limited data on use in human pregnancy and concern regarding potential fetal bone effects and potential nephrotoxicity, tenofovir should be used as a component of maternal combination regimen only after careful consideration of alternatives (**Table 5**).

Among cases of first-trimester didanosine exposure reported to the Antiretroviral Pregnancy Registry, defects have been noted in 4.6% (17/370), compared to a rate of 1.9% (5/257) among those with exposures later in pregnancy *[6]*. All defects were reviewed in detail by the Registry, and no pattern of defects was discovered. However, these data do suggest a possible higher risk of birth defects with exposure to didanosine in the first trimester compared to the frequency of birth defects observed in the general population and with the use of other antiretroviral agents, and the Registry continues to follow this.

Health care providers who are treating HIV-infected pregnant women and their newborns are strongly advised to report instances of prenatal exposure to antiretroviral drugs (either alone or in combination) to the Antiretroviral Pregnancy Registry. This registry is an epidemiologic project to collect observational, nonexperimental data regarding antiretroviral exposure during pregnancy for the purpose of assessing the potential teratogenicity of these drugs. Registry data will be used to supplement animal toxicology studies and assist clinicians in weighing the potential risks and benefits of treatment for individual patients. The Antiretroviral Pregnancy Registry is a collaborative project of pharmaceutical manufacturers with an advisory committee of obstetric and pediatric practitioners. The registry does not use patient names, and registry staff obtain birth outcome follow-up information from the reporting physician.

Combination Antiretroviral Therapy and Pregnancy Outcome

Early data were conflicting as to whether receipt of combination antiretroviral therapy during pregnancy is associated with adverse pregnancy outcomes, in particular preterm delivery. The European Collaborative Study and the Swiss Mother + Child HIV Cohort Study investigated the effects of combination antiretroviral therapy in a population of 3,920 mother-child pairs. Adjusting for CD4 count and intravenous drug use, they found a roughly 2-fold increased odds of preterm delivery for infants exposed to combination therapy with or without protease inhibitors, compared to no treatment; women receiving combination therapy that had been initiated before their pregnancy were twice as likely to deliver prematurely as those starting therapy during the third trimester *[7]*. However, protease inhibitor-based combination therapy was received by only 108 (3%) of the women studied; confounding by severity or indication may have biased the results (i.e., sicker women may have received protease inhibitors more often, but their advanced HIV infection may have actually caused the preterm births). Exposure to NRTI single-drug prophylaxis (primarily zidovudine) was not associated with prematurity. An updated report from the European Collaborative Study including 2,279 mother-child pairs found, in an adjusted analysis, a 1.9-fold increased risk of delivery at less than 37 weeks with combination antiretroviral therapy started during pregnancy and 2.1-fold for combination antiretroviral therapy started prepregnancy compared to mono- or dual-NRTI prophylaxis *[8]*. In this report, 767 women received combination antiretroviral therapy during pregnancy, although the proportion receiving protease inhibitors was not specified. The risk of delivery before 34 weeks of gestation was increased by 2.5-fold for those starting combination antiretroviral therapy during pregnancy and 4.4-fold for those entering pregnancy on combination antiretroviral therapy.

In contrast, in an analysis of 7 prospective clinical studies that included 2,123 HIV-infected pregnant women who delivered infants during 1990–1998 and had received antenatal antiretroviral therapy and 1,143 women who did not receive antenatal antiretroviral therapy, the use of multiple antiretroviral drugs compared to no treatment or treatment with 1 drug was not associated with increased rates of preterm labor, low birth weight, low Apgar scores, or stillbirth *[9]*. Nor were any significant associations between use of antiretrovirals by class or by category, including combination antiretroviral therapy, and adverse pregnancy outcome found in an analysis from the Women and Infants Transmission Study, including 2,543 HIV-infected women (some of whom were included in the previous meta-analysis) *[10]*.

More recent data have continued to be conflicting as to whether preterm delivery is increased with combination antiretroviral therapy. A prospective cohort study including 681 women from Brazil, Argentina, Mexico, and the Bahamas did not find significant associations between use of combination antiretroviral therapy and preterm birth or low birth weight *[11]*. A single-center study from Miami including 1,337 women did find a 1.8-fold increased chance of preterm birth among the 134 women in the cohort who received

protease inhibitor-containing combination antiretroviral therapy compared to other combination therapy, after adjustment for possible confounding variables *[12]*. However, women receiving protease inhibitor-containing combination antiretroviral therapy uniformly were women with advanced disease or those who had failed other combination therapy. The risk of low birth weight and stillbirth were not increased in any therapy groups. A recent meta-analysis of 14 European and American clinical studies found no increase in risk of preterm birth with either antiretroviral therapy compared to no therapy, or combination antiretroviral therapy regimens including protease inhibitors compared to no therapy *[13]*. A slightly increased risk of preterm birth in women who received protease inhibitor combination therapy compared to combination regimens without protease inhibitors was found (OR 1.35; 95% CI, 1.08–1.70).

Other studies have detected small but significant increases (OR of 1.2–1.5 in the largest studies) in preterm birth with protease inhibitor or non-protease inhibitor-based combination antiretroviral therapy as well *[14-17]*. Another variable that may confound these observational studies is the increased rate of preterm birth if combination antiretroviral therapy is begun before conception compared to later during pregnancy, which itself may again reflect confounding by severity or indication *[18]*. When data from the IMPAACT P1025 observational cohort were examined by multivariable analysis to correct for HIV disease stage, protease inhibitor-based combination antiretroviral therapy was no more likely than non-protease inhibitor-based combination antiretroviral therapy to be associated with spontaneous preterm birth (OR 1.22; 95% CI, 0.70–2.12) *[19]*. Clinicians should be aware of a possible increased risk of preterm birth with combination antiretroviral therapy use, but given the clear benefits for maternal health and reduction in perinatal transmission, these agents should not be withheld because of the possibility of increased risk of preterm delivery. Until more information is known, HIV-infected pregnant women who are receiving combination therapy for their HIV infection should continue their provider-recommended regimens. They should receive careful, regular monitoring for pregnancy complications and for potential toxicities.

Nevirapine and Hepatic/Rash Toxicity

Increases in hepatic transaminase levels (ALT and AST) associated with rash or systemic symptoms may be observed during the first 18 weeks of treatment with nevirapine. Signs and symptoms of systemic toxicity may be nonspecific and can include fatigue, malaise, anorexia, nausea, jaundice, liver tenderness, or hepatomegaly, with or without initially abnormal hepatic transaminases *[20]*. The development of severe nevirapine-associated skin rash has been reported to be 5.5 to 7.3 times more common in women than men and has been reported in pregnant women *[21-22]*. Other studies have found that hepatic adverse events with systemic symptoms (predominantly rash) were 3.2-fold more common in women than men *[23-24]*. The degree of risk of hepatic toxicity also appears to vary with CD4 count. In a summary analysis of data from 17 clinical trials of nevirapine therapy, women with CD4 counts >250 cells/mm^3 were 9.8 times more likely than women with lower CD4 counts to experience symptomatic, rash-associated, nevirapine-related hepatotoxicity *[23]*; a single-center study also found higher CD4 counts to be associated with increased risk of severe nevirapine-associated skin rash *[21]*. In controlled clinical trials, clinical hepatic events, regardless of severity, occurred in 4.0% (range 0%–11.0%) of patients who received nevirapine; severe or life-threatening rash occurred in approximately 2% of patients receiving nevirapine *[25]*.

Several early reports of death due to hepatic failure in HIV-infected pregnant women receiving nevirapine as part of a combination antiretroviral regimen raised concerns that pregnant women might be at increased risk of hepatotoxicity from nevirapine compared to other antiretroviral drugs *[26-27]*. Recent data challenge the notion that nevirapine is uniquely associated with increased hepatotoxicity during pregnancy *[28]*. In an analysis of two multi-center prospective cohorts, pregnancy itself was a risk factor for liver enzyme elevations (RR 4.7; 5% CI; 3.4–6.5), but nevirapine use was not, regardless of pregnancy status *[28]*. Further data from the same cohorts did not show any increased risk of hepatotoxicity in HIV-infected pregnant women receiving nevirapine-based combination antiretroviral therapy versus non-nevirapine-based combination antiretroviral therapy *[29]*. These data suggest that nevirapine is no more toxic in pregnant women than in nonpregnant women.

Nevertheless, if nevirapine is used in pregnancy, health care providers should be aware of potential hepatotoxicity with or without rash and should conduct frequent and careful monitoring of clinical symptoms and hepatic transaminases (i.e., ALT and AST), particularly during the first 18 weeks of therapy. Some clinicians measure serum transaminases at baseline, every 2 weeks for the first month, monthly through month 4, and every 1 to 3 months thereafter (see the *Hepatotoxicity* section of Table 12 in the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***). In patients with pre-existing liver disease, monitoring should be performed more frequently when initiating therapy and then monthly *[20]*. Transaminase levels should be checked in all women who develop a rash while receiving nevirapine. Patients who develop suggestive clinical symptoms accompanied by elevation in serum transaminase levels (ALT and/or AST) or who have asymptomatic but severe transaminase elevations (i.e., >5 times the upper limit of normal) should stop nevirapine and not receive nevirapine therapy in the future.

Hepatic toxicity has not been seen in women receiving single-dose nevirapine during labor for prevention of perinatal transmission of HIV *[30]*. Women who enter pregnancy on nevirapine-containing regimens and are tolerating them well may continue therapy, regardless of CD4 count.

NRTI Drugs and Mitochondrial Toxicity

NRTI drugs are known to induce mitochondrial dysfunction because the drugs have varying affinity for mitochondrial gamma DNA polymerase. This affinity can interfere with mitochondrial replication, resulting in mitochondrial DNA depletion and dysfunction *[31]*. The relative potency of the NRTI drugs in inhibiting mitochondrial gamma DNA polymerase *in vitro* is highest for zalcitabine, followed by didanosine, stavudine, zidovudine, lamivudine, abacavir, and tenofovir *[32]*. In a recent study, didanosine and didanosine-containing regimens were associated with the greatest degree of mitochondrial suppression *[33]*. Toxicity related to mitochondrial dysfunction has been reported to occur in infected patients receiving long-term treatment with NRTI drugs and generally has resolved with discontinuation of the drug or drugs; a possible genetic susceptibility to these toxicities has been suggested *[31]*. These toxicities may be of particular concern for pregnant women and infants with *in utero* exposure to NRTI drugs.

During Pregnancy

Clinical disorders linked to mitochondrial toxicity include neuropathy, myopathy, cardiomyopathy, pancreatitis, hepatic steatosis, and lactic acidosis. Among these disorders, symptomatic lactic acidosis and hepatic steatosis may have a female preponderance *[34-35]*. These syndromes have similarities to rare but life-threatening syndromes that occur during pregnancy, most often during the third trimester: acute fatty liver and the syndrome of hemolysis, elevated liver enzymes, and low platelets (the HELLP syndrome). Data suggest that a disorder of mitochondrial fatty acid oxidation in the mother or her fetus during late pregnancy may play a role in the development of acute fatty liver of pregnancy and HELLP syndrome *[36-39]* and possibly contribute to susceptibility to antiretroviral-associated mitochondrial toxicity. HELLP may also occur postpartum among women with severe pre-eclampsia *[40]*. In addition to low platelets and elevated liver enzymes, other laboratory findings reported among HIV-infected pregnant women on antiretroviral therapy include mitochondrial placental depletion but without evidence of ultrastructual damage to placental cells. The clinical significance of reduced mitochondrial DNA in placentas exposed to antiretroviral drugs remains unknown *[41]*.

Lactic acidosis with microvacuolar hepatic steatosis is a toxicity related to NRTI drugs that is thought to be related to mitochondrial toxicity; it has been reported to occur in infected persons treated with NRTI drugs for long periods (>6 months). In a report from the FDA Spontaneous Adverse Event Program, typical initial symptoms included 1 to 6 weeks of nausea, vomiting, abdominal pain, dyspnea, and weakness *[42]*. Metabolic acidosis with elevated serum lactate and elevated hepatic enzymes was common. Patients described in that report were predominantly female and overweight.

The incidence of this syndrome may be increasing, possibly as a result of increased use of combination NRTI therapy or increased recognition of the syndrome.

The frequency of this syndrome in pregnant HIV-infected women receiving NRTI drugs is unknown. In 1999, Italian researchers reported a case of severe lactic acidosis in an infected pregnant woman who was receiving stavudine-lamivudine at the time of conception and throughout pregnancy and who experienced symptoms and fetal death at 38 weeks gestation *[43]*. Bristol-Myers Squibb has reported three maternal deaths due to lactic acidosis, two with and one without accompanying pancreatitis, among women who were either pregnant or postpartum and whose antepartum therapy during pregnancy included stavudine and didanosine in combination with other antiretroviral agents (either a protease inhibitor or nevirapine) *[44-45]*. All women were receiving treatment with these agents at the time of conception and continued for the duration of pregnancy; all presented late in gestation with symptomatic disease that progressed to death in the immediate postpartum period. Two cases were also associated with fetal death. Nonfatal cases of lactic acidosis in pregnant women receiving combination stavudine-didanosine also have been reported *[46]*.

It is unclear if pregnancy augments the incidence of the lactic acidosis/hepatic steatosis syndrome that has been reported for nonpregnant persons receiving NRTI drugs. However, because pregnancy itself can mimic some of the early symptoms of the lactic acidosis/hepatic steatosis syndrome or be associated with other disorders of liver metabolism, these cases emphasize the need for physicians caring for HIV-infected pregnant women receiving NRTI drugs to be alert for early signs of this syndrome.

Additionally, because of the reports of several cases of maternal mortality secondary to lactic acidosis with prolonged use of the combination of stavudine and didanosine by HIV-infected pregnant women, clinicians should not prescribe this antiretroviral combination during pregnancy. The combination stavudine-didanosine is also not recommended for nonpregnant adults.

In Utero Exposure

It has been suggested that mitochondrial dysfunction might develop in infants with *in utero* exposure to NRTI drugs. Data from a French cohort of 1,754 uninfected infants born to HIV-infected women who received antiretroviral drugs during pregnancy identified 8 infants with *in utero* or neonatal exposure to either zidovudine/lamivudine (4 infants) or zidovudine alone (4 infants) who developed indications of mitochondrial dysfunction after the first few months of life *[47]*. Two of these infants (both exposed to zidovudine/lamivudine) contracted severe neurologic disease and died; 3 had mild to moderate symptoms; and 3 had no symptoms but had transient laboratory abnormalities. In a larger cohort of 4,392 uninfected children (including the children in the previous study) followed within the French Pediatric Cohort or identified within a French National Register, the 18-month incidence of clinical symptoms of mitochondrial dysfunction was 0.26% and 0.07% for mortality *[48]*. All children had perinatal antiretroviral exposure; risk was higher among infants exposed to combination antiretroviral drugs (primarily zidovudine/lamivudine) than to zidovudine alone. The children presented with neurologic symptoms, often with abnormal magnetic resonance imaging and/or episode of significant hyperlactatemia, and deficits in mitochondrial respiratory chain complex enzyme function on biopsy of muscle. The same group also has reported an increased risk of simple febrile seizures in the first 18 months of life and persistently lower (but clinically insignificant) neutrophil, lymphocyte, and platelet counts in infants with *in utero* NRTI exposure *[49-50]*. More recently, in continued follow-up of the French Perinatal Cohort, researchers reported severe neurologic symptoms in the first 2 years of life as a rare event (0.30.5%) *[51]*.

Clinical studies in the United States and Europe generally have not duplicated the French reports *[52-58]*. The Perinatal Safety Review Working Group performed a retrospective review of deaths occurring

among children born to HIV-infected women and followed during 1986–1999 in 5 large prospective U.S. perinatal cohorts. No deaths similar to those reported from France or with clinical findings attributable to mitochondrial dysfunction were identified in a database of >16,000 uninfected children born to HIV-infected women with and without antiretroviral drug exposure *[53]*. However, most of the infants with antiretroviral exposure had been exposed to zidovudine alone and only a relatively small proportion (approximately 6%) had been exposed to zidovudine/lamivudine. The European Collaborative Study reviewed clinical symptoms in 2,414 uninfected children in their cohort with median follow-up of 2.2 years (maximum, 16 years); 1,008 had perinatal antiretroviral exposure *[55]*. No association of clinical manifestations suggestive of mitochondrial abnormalities was found with perinatal antiretroviral exposure. Of the 4 children with seizures in this cohort, none had perinatal antiretroviral exposure. In a report from a long-term follow-up study in the United States (PACTG 219/219C), 20 children with possible symptoms of mitochondrial dysfunction were identified in a cohort of 1,037 uninfected infants born to HIV-infected mothers *[57]*. Definitive diagnosis was not available because none of the children had biopsies for mitochondrial function. Three of the 20 children had no exposure to antiretroviral drugs. In the 17 remaining children, although overall exposure to NRTI drugs was not associated with symptoms, there was an association of symptoms with first exposure to zidovudine/lamivudine limited to the third trimester.

Laboratory abnormalities without clinical symptoms have been reported among infants with perinatal antiretroviral exposure compared to unexposed infants in a number of studies, most of which are limited by small numbers of subjects. In 1 study, mitochondrial DNA quantity was lower in cord and peripheral blood white cells at age 1 and 2 years among 20 infants born to HIV-infected women compared to 30 infants born to uninfected women and was lowest among 10 HIV-exposed infants with zidovudine exposure compared to 10 without zidovudine exposure *[59]*. In a subsequent study, mitochondrial changes were evaluated in umbilical cord endothelial cells and cord blood from human infants and monkeys with *in utero* exposure to various NRTI-containing regimens *[60]*. Similar morphologic changes and mitochondrial DNA depletion were seen in the human and monkey infants. In the monkeys, mitochondrial damage demonstrated a gradient with greatest damage with stavudine/lamivudine > zidovudine/didanosine > zidovudine/lamivudine > lamivudine. In a Canadian study of 73 antiretroviral-exposed infants and 81 controls with blood samples during the first 8 months of life, investigators found that in the first weeks of life, blood mitochondrial DNA levels were higher and blood mitochondrial RNA levels were lower in the HIV- and antiretroviral-exposed infants compared to infants without HIV and antiretroviral exposure *[61]*. In another study, transient hyperlactatemia during the first few weeks of life was reported among 17 HIV-exposed infants with perinatal antiretroviral exposure; lactate levels returned to normal in all children and none developed symptoms of mitochondrial dysfunction during follow-up *[62]*. Similarly, the French Perinatal cohort study has reported asymptomatic hyperlactatemia in one-third of zidovudine-exposed newborns, which resolved following perinatal drug exposure *[51]*. Clinically asymptomatic hematologic findings have been reported by several investigators among uninfected infants with *in utero* exposure to antiretroviral therapy in the United States and Europe *[63-65]*, and infants with triple combination antiretroviral therapy exposure were found to be at increased risk of lowered hemoglobin compared to those with perinatal exposure to zidovudine or zidovudine/lamivudine *[66]*. The clinical significance of these laboratory findings is unclear, and further long-term studies are needed to validate the findings and assess the degree to which they affect growth and development of infants exposed to antiretroviral therapy.

Thus, there are conflicting data regarding whether mitochondrial dysfunction is associated with perinatal antiretroviral exposure, and further studies are needed. Even if an association is more clearly demonstrated, the development of severe or fatal mitochondrial disease appears to be extremely rare and should be compared to the clear benefit of antiretroviral prophylaxis in reducing transmission of a fatal infection by 70% or more *[55, 67-68]*. Mitochondrial dysfunction should be considered in uninfected children with perinatal antiretroviral exposure who present with severe clinical findings of unknown etiology, particularly neurologic findings. These results emphasize the importance of the

existing HHS recommendation for long-term follow-up for any child with *in utero* exposure to antiretroviral drugs.

Protease Inhibitor Therapy and Hyperglycemia

Hyperglycemia, new-onset diabetes mellitus, exacerbation of existing diabetes mellitus, and diabetic ketoacidosis have been reported with receipt of protease inhibitor antiretroviral drugs by HIV-infected patients *[69-72]*. In addition, pregnancy is itself a risk factor for hyperglycemia. However, the majority of data to date have not shown an increased risk of glucose intolerance with protease inhibitor therapy during pregnancy. One small retrospective study that included 41 women receiving protease inhibitor-based combination antiretroviral therapy found an increased risk of glucose intolerance, but not gestational diabetes, among women on combination antiretroviral therapy compared to zidovudine alone *[73]*, while two other retrospective studies did not find an increased risk of glucose intolerance with protease inhibitors *[74-75]*. Secondary analyses of two large cohorts did not find an association with type of antiretroviral therapy and gestational diabetes, except for an association of protease inhibitor initiation before pregnancy or during the first trimester and gestational diabetes in the PACTG 316 cohort *[10, 76]*. Finally, a prospective study including detailed evaluations for glucose intolerance and insulin resistance among HIV-infected pregnant women did not find differences between women on protease inhibitor-containing and non-protease inhibitor-containing regimens *[77]*. The rate of impaired glucose tolerance was high (38%) in both groups, likely related to high body mass index and race/ethnicity among trial subjects.

HIV-infected women receiving antiretroviral therapy during pregnancy should receive standard glucose screening with a standard, 1-hour, 50-gram glucose loading test at 24 to 28 weeks of gestation. Some experts would perform earlier glucose screening in women with ongoing protease inhibitor-based therapy initiated prior to pregnancy (particularly in women of minority race/ethnicity), similar to recommendations for women with high-risk factors for glucose intolerance, such as maternal obesity, advanced maternal age, and family history of type II diabetes mellitus.

ANTIRETROVIRAL DRUG RESISTANCE AND RESISTANCE TESTING IN PREGNANCY

Indications for Antiretroviral Drug Resistance Testing in HIV-Infected Pregnant Women

Panel's Recommendations:

- ***HIV drug resistance testing is recommended for:***
  - ***All pregnant women not currently receiving antiretroviral drugs, before starting treatment or prophylaxis (AIII).***
  - ***All pregnant women receiving antenatal antiretroviral therapy who have persistently detectable HIV RNA levels (AI) or who have suboptimal viral suppression after initiation of antiretroviral therapy (AII).***
- ***For optimal prevention of perinatal transmission, empiric initiation of antiretroviral therapy before results of resistance testing are available may be warranted, with adjustment as needed after the test results are available (BIII).***

Resistance testing is recommended for all antiretroviral-naïve pregnant women before initiating treatment or prophylaxis if prior resistance testing has not been done. For details regarding genotypic and phenotypic resistance testing see ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***. Ideally, resistance testing would be done at a preconception visit to allow receipt of results and selection of an antiretroviral drug regimen to be used during pregnancy or started before pregnancy if maternal therapy is indicated. There is accumulating evidence that:

- transmitted resistant mutants may persist for indefinite periods after initial infection;
- these viral variants may be detectable by standard assays used in clinical practice;
- the prevalence of resistance in antiretroviral-naïve patients is increasing; and
- previous resistance may be associated with adverse virologic outcomes *[1-8]*.

For these reasons, resistance testing is now recommended for all pregnant women prior to initiating antiretroviral drugs for treatment or prophylaxis of mother-to-child transmission of HIV *[9-10]*.

Resistance testing should also be performed before initiation of therapy or prophylaxis in pregnant women who received prophylaxis in previous pregnancies and are now restarting antiretroviral drugs for prevention of perinatal transmission. There are no data currently addressing the utility of resistance testing in the setting of pregnancy, when short-term prophylactic therapy is often initiated in women who do not yet need treatment for their own disease, and women who have multiple pregnancies may undergo several periods of antiretroviral prophylaxis to prevent mother-to-child transmission. The identification of baseline resistance mutations may allow selection of more effective and more durable antiretroviral regimens in women needing treatment and greater preservation of future treatment options in women receiving antiretroviral therapy only for perinatal prophylaxis. However, there is no evidence that baseline resistance testing in pregnancy is associated with a reduction in perinatal transmission rates.

For pregnant women already receiving antiretroviral therapy at the time they present for obstetrical care or are seen for follow-up after initiation of therapy, resistance testing is indicated if there is suboptimal initial viral suppression following initiation of antiretroviral therapy or virologic failure on the current regimen as signified by persistently detectable HIV RNA levels.

In most settings, the results of resistance testing guide selection of the initial antiretroviral regimen. However, in some clinical situations, the clinician may choose to initiate empiric antiretroviral therapy or prophylaxis before resistance testing results are available in order to maximize prevention of perinatal transmission. Once resistance test results are obtained, the antiretroviral drug regimen may be modified as needed. Such situations

include when women have initial resistance testing in the third trimester and test results may not be back in time to allow effective reduction of viral load before delivery. If results of resistance testing performed in the latter half of a woman's pregnancy cannot be obtained within 7 days, most experts believe that the benefits of immediate initiation of antiretroviral drugs—taking into account a woman's previous antiretroviral history—outweigh the possible risk of initiating a regimen that could be suboptimal due to pre-existing resistance.

Significance of Antiretroviral Drug Resistance in Pregnancy

The development of antiretroviral drug resistance is one of the major factors leading to therapy failure in HIV-infected persons. Resistant viral variants emerge under selective pressure, especially with incompletely suppressive regimens, because of the mutation-prone process of reverse transcription in viral replication. Although specific resistance mutations may become undetectable when selective drug pressure is removed, resistant viral variants are believed to be archived permanently in latent HIV reservoirs and can re-emerge with re-exposure to drugs to which decreased susceptibility had been established *[11]*. The administration of combination antiretroviral regimens with maximal suppression of viral replication to undetectable levels limits the development of antiretroviral resistance in both pregnant and nonpregnant persons.

In addition to the concerns about development of drug resistance in the general population, pregnancy presents some special concerns related to the development of drug resistance. Pre-existing resistance to a drug in an antiretroviral prophylaxis regimen may diminish efficacy of that regimen in preventing perinatal transmission. Development of resistance to drugs used during pregnancy for prophylaxis of perinatal transmission may limit future maternal treatment options or decrease the effectiveness of prophylactic regimens in the current pregnancy or future pregnancies. Additionally, if maternal resistance is present or develops and resistant virus is transmitted, infant treatment options may be limited.

Several factors unique to pregnancy may increase the chance of development of resistance. Antiretroviral drugs may be used during pregnancy solely for prophylaxis of perinatal transmission and discontinued after delivery in women who do not require therapy for their own health. If regimens used for prophylaxis include drugs with significant differences in half-life, such as nevirapine or efavirenz combined with two nucleoside analogue drugs, discontinuation of all regimen components simultaneously postpartum may result in persistent subtherapeutic drug levels and increase the risk of development of NNRTI resistance (see **Stopping Antiretroviral Therapy during Pregnancy**). Problems such as nausea and vomiting in early pregnancy may compromise adherence and increase the risk of resistance in women receiving antiretroviral treatment.

Prevalence of Antiretroviral Drug Resistance

General Population

The reported prevalence of antiretroviral drug resistance varies depending on several factors, including characteristics of the population studied (e.g., newly infected versus chronically infected), prior and current exposure to antiretroviral drugs and type of regimen (HAART versus non-HAART), geographic area, and type of resistance assay used (genotypic versus phenotypic). In genotypic resistance surveys of newly infected, therapy-naïve persons conducted in the United States and Europe, rates of primary resistance mutations appear to be increasing over time and have been reported as high as 23% *[5, 12-13]*. The presence of high-level phenotypic resistance (>10-fold increase in 50% inhibitory concentration [IC50]) increased from 3.4% in 1995–1998 to 12.4% in 1999–2000 in a retrospective analysis from 10 U.S. cities and was associated with longer time to viral suppression and shorter time to virologic failure *[12]*.

Other studies have examined antiretroviral drug resistance in treatment-naïve persons with newly diagnosed HIV infection of unknown duration. In this population more typical of patients presenting for initial evaluation and care, 8.3% to 10.8% of patients had HIV with genotypic mutations associated with reduced antiretroviral

susceptibility, with prevalence increasing over time *[4-5]*. The highest rates of antiretroviral drug resistance have been reported in antiretroviral treatment-experienced individuals, with resistance rates as high as 88% reported in viremic individuals currently receiving therapy and 30% in individuals with a past history of treatment *[14]*.

Pregnancy

Data about the prevalence of antiretroviral drug resistance in pregnant women are limited. The available data suggest that rates of resistance are similar in pregnant women and in nonpregnant individuals, with antiretroviral drug resistance more frequent among antiretroviral-experienced women. A study from a university hospital in St. Louis found that 3 (17%) of 18 antiretroviral-naïve pregnant women followed at the hospital had primary genotypic resistance to NNRTI drugs, which was equal to the overall prevalence of such resistance in the antiretroviral-naïve population in the same city *[15]*. In a retrospective review of 45 consecutive HIV-infected pregnant women with amplifiable virus presenting for care in New York, 0 of 22 antiretroviral-naïve pregnant women and 11 (48%) of 23 antiretroviral-experienced women had major drug resistance mutations *[16]*. Among 220 pregnant antiretroviral-experienced women in the Perinatal AIDS Collaborative Transmission Study (PACTS), all of whom had prior zidovudine exposure in pregnancy from 1991 to 1997, 17.3% had zidovudine-associated mutations *[17]*. In a substudy of the Pediatric AIDS Clinical Trials Group (PACTG) Protocol 316, an international, multi-center clinical trial comparing single-dose nevirapine with placebo in HIV-infected pregnant women receiving standard antiretroviral therapy, 7 (3.2%) of 217 women with detectable HIV RNA had mutations associated with nevirapine resistance at 6 weeks postpartum, despite no history of prior exposure to non-nucleoside drugs or receipt of nevirapine at delivery *[18]*. Additionally, more than 60% of women receiving combination therapy (either dual nucleosides or combinations containing a PI) had the M184V mutation conferring resistance to lamivudine, and 25 (11%) of 217 women had primary or secondary protease mutations.

Despite the increasing prevalence of drug resistance in treatment-naïve and -experienced individuals, there is currently no evidence to indicate on a population basis that antiretroviral drug resistance in HIV-infected pregnant women is compromising the efficacy of perinatal HIV prevention efforts in North America or Europe, where mother-to-child transmission rates remain less than 2% *[19-20]*.

Incidence of Antiretroviral Resistance with Perinatal Prophylactic Regimens

The presence of mutations conferring resistance to nucleoside analogue drugs appears to be correlated with more advanced maternal disease and duration of prior or current exposure to these drugs *[17, 21-23]*. Development of zidovudine drug resistance when zidovudine is used alone appears uncommon in women with higher CD4 count and low viral load *[24-25]* but is more of a concern in women who have more advanced disease and lower CD4 count *[21]*.

Nevirapine also has a low genetic barrier to resistance, with 1 point mutation conferring resistance to nevirapine and to other NNRTI drugs. Furthermore, its long half-life, with blood levels detectable up to 21 days after a single dose in labor, increases selection pressure and risk of resistance *[26]*. Factors associated with increased risk of resistance following single-dose nevirapine exposure include high baseline viral load, low baseline CD4 cell count, viral subtype, and number of maternal doses. The rate of genotypic resistance after exposure to single-dose nevirapine has varied in studies, ranging from 15% to 75% *[18, 27-36]*. Studies using more sensitive real-time polymerase chain reaction (PCR) techniques suggest that up to one-half of resistance that develops is not detected by conventional sequence analysis *[35-38]*. However, these studies demonstrate that although resistance occurs in the first few weeks post-exposure in the majority of women exposed to single-dose nevirapine, the prevalence of resistance declines rapidly over time and the proportion of resistant virus in those with detectable virus 12 months after exposure is low; additionally, archiving of resistance in cellular provirus may be infrequent. In a study of virus from 67 South African women, using a sensitive allele-specific resistance assay, the K103N mutation was seen in 87% of women at 6 weeks but in

only 11% at 12 months after single-dose nevirapine exposure, with a median frequency of the mutation of 0.7% (range 0.5%–5.4%) in women with detectable resistance at 12 months. The K103N mutation was found in cellular DNA in only 4.2% of women at 12 months post-exposure *[38]*. A recent study has examined the presence of resistant mutations in HIV-1-infected women receiving antiretrovirals limited to pregnancy. All women evaluated received zidovudine and lamivudine with 76% receiving nelfinavir and 8% nevirapine. In women receiving dual or triple prophylaxis, postpartum rates of the M184V/I mutations were 65% and 29%, respectively. NNRTI resistance was identified postpartum among 38% of nevirapine recipients, whereas only 1% of PI recipients developed resistance *[39]*.

Addition of single-dose nevirapine to other background regimens (77% of women received antenatal combination antiretroviral therapy) still resulted in nevirapine resistance in 14 of 95 (15%; 95% CI, 8%–23%) women in the PACTG 316 study *[18]*. Because PACTG 316 demonstrated that the addition of single-dose nevirapine in situations where combination antiretroviral therapy is being received did not provide any additional efficacy in prevention of mother-to-child transmision, and because there is a risk of nevirapine resistance, this approach is not recommended.

Impact of Resistance in Pregnancy

Perinatal Transmission

Although perinatal transmission of resistant virus has been reported, it appears to be unusual, and there is little evidence that the presence of resistant mutations increases the risk of transmission when current recommendations for antiretroviral management in pregnancy are followed. A substudy of the Women and Infants Transmission Study followed pregnant women receiving zidovudine alone for treatment of HIV disease in the early 1990s. In this study, detection of zidovudine resistance conferred an increased risk of transmission when analysis was adjusted for duration of membrane rupture and total lymphocyte count *[21]*; however, women in this cohort had characteristics that would indicate treatment with combination antiretroviral therapy under the current HHS recommendations for maternal health and for prevention of perinatal transmission. When transmitting mothers had mixed viral populations of wild-type and virus with low-level zidovudine resistance, only wild-type virus was found in the infant *[40]*, and other studies have suggested that drug resistance mutations may diminish the fitness of the virus *[41]*, possibly leading to a decrease in transmissibility. The prevalence of antiretroviral drug resistance was examined among HIV-infected newborns in New York State. Eleven (12.1%) of 91 infants born in 1989–1999 and 8 (19%) of 42 infants born in 2001–2002 had mutations associated with decreased drug susceptibility. However, perinatal antiretroviral exposure was not found to be a significant risk factor for the presence of resistance in either time period *[42-43]*. Neither resistance to nevirapine that develops as a result of exposure to single-dose nevirapine nor exposure to single-dose nevirapine in a prior pregnancy has been shown to affect perinatal transmission rates *[44-45]*.

Maternal Response to Subsequent Treatment Regimens

Because nevirapine resistance mutations can be detected in the postpartum period in a significant proportion of women receiving single-dose intrapartum/infant nevirapine prophylaxis, the response to non-nucleoside-based combination therapy when later required for maternal health reasons has been a concern *[30, 38, 44-47]*. The Optimal Combination Therapy After Nevirapine Exposure (OCTANE)/A5208 trial conducted in Africa compared nevirapine versus lopinavir/ritonavir-based therapy in women requiring therapy who had prior exposure to single-dose nevirapine prophylaxis. The results suggest that prior exposure to single-dose nevirapine within 24 months of initiating therapy may be associated with higher risk of viral failure with nevirapine-based therapy compared to lopinavir/ritonavir-based therapy. In this study, significantly more women in the nevirapine arm (29, 24%) failed to achieve undetectable viral load (25) or died (4) compared to women in the lopinavir/ritonavir arm (8, 7%; 7 virologic failures and 1 death; $p < 0.0005$). Of those women with documented nevirapine resistance at the start of therapy, 38% (5 of 13) either had detectable virus or died. One caveat to the OCTANE study, however, is that the women who received lopinavir/ritonavir had a 93%

rate of viral suppression, a percentage substantially greater than that found in comparable studies. However, this study further supports that women with documented nevirapine resistance are most likely to benefit from combination therapy that does not contain nevirapine (and because of cross-resistance, efavirenz) *[48]*.

There are few data evaluating response to subsequent therapy in women who receive current combination drug regimens for prophylaxis and discontinue the drugs postpartum. However, if the regimen that was discontinued had fully suppressed viral replication, theoretically, resistance should not occur. Issues relating to discontinuation of nevirapine-based combination therapy are discussed in the section **Prevention of Antiretroviral Drug Resistance**.

Management of Antiretroviral Drug Resistance during Pregnancy

Panel's Recommendations:

- ***Women who have documented zidovudine resistance and are on regimens that do not include zidovudine for their own health should still receive intravenous zidovudine during labor whenever possible, along with their established antiretroviral regimens and postnatal oral zidovudine for their infants (AII). For women who are receiving a stavudine-containing regimen, stavudine should be discontinued during labor while intravenous zidovudine is being administered (see Intrapartum Care).***
- ***The optimal prophylactic regimen for newborns of women with antiretroviral resistance is unknown (see Infant Antiretroviral Prophylaxis). Therefore, antiretroviral prophylaxis for an infant born to a woman with known or suspected drug resistance should be determined in consultation with a pediatric HIV specialist, preferably before delivery (AIII).***

Ideally, antiretroviral regimens used during pregnancy for treatment or prophylaxis should be chosen based on the results of antiretroviral resistance testing. However, antiretroviral drugs are also used during pregnancy for prevention of mother-to-child transmission. Although most transmission occurs during the intrapartum period, 30% to 35% of transmission may occur *in utero [49-51]*; the majority of *in utero* infection is thought to occur later in pregnancy *[49]* and may be more likely in women with advanced HIV disease and/or high viral load *[50-51]*. Therefore, delay in initiation of an antiretroviral drug regimen to await results of resistance testing could result in *in utero* infection of the infant, particularly in women at high risk of transmission or who are late in pregnancy at the time the drugs are initiated. In such circumstances, as noted earlier, empiric initiation of antiretroviral prophylaxis may be warranted to maximize prevention of perinatal transmission, with the regimen modified if needed once resistance testing results become available.

For women who have documented zidovudine resistance and whose antepartum regimen does not include zidovudine, intravenous zidovudine during labor should still be administered whenever possible (see **Intrapartum Care**). If the woman's antepartum regimen includes stavudine, which may be antagonistic to zidovudine, stavudine should be stopped during the intrapartum period and restarted after delivery (see **Intrapartum Care**). Other antiretrovirals should be continued orally during labor to the extent possible. Zidovudine should also be administered orally to the infant for 6 weeks. For an infant born to a woman with known zidovudine-resistant virus, many clinicians would choose to provide additional antiretroviral agents to the infant in combination with zidovudine (see **Infant Antiretroviral Prophylaxis**). Such a decision must be accompanied by a discussion with the woman of the potential benefits and risks of this approach and the lack of data to address its efficacy and safety. The optimal prophylactic regimen for newborns of women with antiretroviral drug-resistant virus is unknown. Therefore, antiretroviral prophylaxis for the infant born to a woman with known or suspected drug-resistant virus should be determined with a pediatric HIV specialist, preferably before delivery.

The rationale for including zidovudine intrapartum and to the infant when a woman is known to harbor virus with zidovudine resistance is based on several factors. Data thus far have suggested that when mothers have mixed populations of wild-type virus and virus with low-level zidovudine resistance, only wild-type virus is

found in the infant *[40]*. Other studies have suggested that drug resistance mutations may diminish viral fitness and possibly decrease transmissibility *[41]*. Efficacy of the zidovudine prophylaxis appears to be based not only on reduction of HIV levels in the mother but also on pre- and post-exposure prophylaxis in the infant *[52-54]*. Zidovudine crosses the placenta readily and has one of the highest maternal-to-cord blood ratios among the nucleoside analogue agents. Additionally, zidovudine is metabolized to the active triphosphate within the placenta *[55-56]*, which may provide additional protection against transmission. Metabolism to the active triphoshate, which is required for activity of all nucleoside analogue agents, has not been observed within the placenta with other nucleoside analogues that have been evaluated (didanosine and zalcitabine) *[57-58]*. In addition, zidovudine has been shown to reduce genital HIV RNA levels, and genital viral levels have been shown to correlate with perinatal transmission *[59]*. Data on levels of other nucleoside analogues in the genital tract are more limited, and it is unknown if other nucleoside analogue agents will provide a similar reduction in genital tract HIV RNA levels *[60-62]*. Zidovudine has better penetration into the central nervous system (CNS) compared to other nucleoside analogues with the exception of stavudine, whose CNS penetration is similar; this may help to eliminate a potential reservoir for transmitted HIV in the infant *[63-64]*. Thus, intravenous intrapartum and oral zidovudine for the infant should be included even in the presence of known zidovudine resistance because of the unique characteristics of zidovudine and its proven record in reducing perinatal transmission.

Prevention of Antiretroviral Drug Resistance

Panel's Recommendations:

- ***HIV-infected pregnant women should use combination antiretroviral drug regimens to maximally suppress viral replication; this is the most effective strategy to prevent the development of resistance and to minimize the risk of perinatal transmission (AII).***
- ***All pregnant women should be counseled about the importance of adherence to prescribed antiretroviral medications to reduce the potential for development of resistance (AII).***
- ***For pregnant women receiving an NNRTI-based combination antiretroviral therapy regimen for prophylaxis only, with plans to discontinue therapy after delivery, the nucleoside analogue agents should be given for at least 7 days after stopping the NNRTI to minimize the risk of resistance (AI). An alternative strategy is to substitute a PI for the NNRTI prior to the interruption and to continue the PI with dual NRTIs. The optimal interval between stopping an NNRTI and the other antiretroviral drugs is not known. Given the potential of prolonged detectable NNRTI concentrations for more than 3 weeks in patients receiving efavirenz-based therapy, some experts recommend continuing the other antiretroviral agents or substituting a PI plus two other agents for up to 30 days. (CIII) (See Stopping Antiretroviral Therapy during Pregnancy and Postpartum Follow-Up of HIV-Infected Women.)***
- ***The addition of single-dose maternal/infant nevirapine to an ongoing combination antiretroviral treatment or prophylaxis regimen does not provide additional efficacy in reducing perinatal transmission and may result in nevirapine drug resistance in the mother and/or infant; therefore single-dose maternal/infant nevirapine is not recommended in this situation (AI).***

The most effective way to prevent the development of antiretroviral drug resistance in pregnancy is to use and adhere to an effective combination of antiretroviral drugs to achieve maximal viral suppression. Selection of a regimen should take into account prior antiretroviral treatment history, including documented clinical, immunologic, or virologic failure with or without genotypic or phenotypic resistance testing; history of nonadherence; and problems with intolerance.

When nevirapine or other NNRTI drugs are used as part of a prophylactic combination antiretroviral regimen that is stopped after delivery, there is a risk of development of NNRTI resistance because of the drug's prolonged half-life, leading to a period of persistent subtherapeutic levels of a single drug if all drugs are discontinued at once. Studies in South Africa and Cote d'Ivoire have shown that the development of

nevirapine resistance following exposure to single-dose intrapartum nevirapine (given alone or in combination with antenatal antiretroviral therapy) was significantly decreased (but not eliminated) if zidovudine/lamivudine was given intrapartum and administered for 3 to 7 days postpartum after intrapartum nevirapine *[65-66]*. In a cohort of 39 women who initiated combination antiretroviral therapy in pregnancy and had genotypic testing performed at 6 weeks postpartum, 5 (13%) had primary mutations detected *[31]*. All 5 were on combination regimens that included nevirapine, were treatment naïve prior to pregnancy, and had staggered drug discontinuation after delivery (the dual nucleoside component of the regimen was continued for 5 days after stopping nevirapine). It is not known whether the incidence of resistance would have been significantly higher if drug discontinuation had not been staggered. An alternative strategy is to substitute a PI for the NNRTI and to continue the PI with dual NRTIs for a period of time *[67]*. The optimal duration needed to continue either dual nucleosides or the substituted PI-based regimen after stopping the NNRTI is not known. NNRTI drugs have long half-lives, and drug levels can persist for up to 1 to 3 weeks after stopping the drug; efavirenz levels persist longer than nevirapine levels *[26, 68]*. Further research is needed on the optimal duration of time and regimen to "cover" this period of prolonged NNRTI exposure to prevent the emergence of resistance following discontinuation of NNRTI-based therapy. Many experts will stop the NNRTI drug and continue the other antiretroviral drugs for at least 7 days, although other experts would recommend up to 30 days, particularly if an efavirenz-based regimen is being stopped.

Intrapartum Care (Updated May 24, 2010)

INTRAPARTUM ANTIRETROVIRAL THERAPY/PROPHYLAXIS

Panel's Recommendations:

- ***Intrapartum intravenous zidovudine is recommended for all HIV-infected pregnant women, regardless of their antepartum regimen, to reduce perinatal transmission of HIV (AI).***
- ***For women who are receiving a stavudine-containing antepartum regimen, stavudine should be discontinued during labor while intravenous zidovudine is being administered (AI).***
- ***Women who are receiving an antepartum combination antiretroviral treatment regimen should continue this regimen on schedule as much as possible during labor and prior to scheduled cesarean delivery (AIII).***
- ***Women receiving fixed-dose combination regimens that include zidovudine should have zidovudine administered intravenously during labor while other antiretroviral components are continued orally (AIII).***
- ***For women who have received antepartum antiretroviral drugs but have suboptimal viral suppression near delivery (i.e., >1,000 copies/mL), scheduled cesarean delivery is recommended (AI). The addition of single-dose intrapartum/newborn nevirapine is generally not recommended (AI).***
- ***Women of unknown HIV status who present in labor should have rapid HIV antibody testing performed (AII). If the test is positive, a confirmatory HIV test should be sent as soon as possible and maternal/infant antiretroviral drugs should be initiated without waiting for results of the confirmatory test (AII). If the confirmatory HIV test is positive, antiretroviral drugs should be continued in the infant for 6 weeks (see Neonatal Postnatal Care) (AI); if the test is negative, the infant antiretroviral drugs should be stopped.***
- ***For HIV-infected women in labor who have not received antepartum antiretroviral drugs, intravenous zidovudine during labor and 6 weeks of infant zidovudine are recommended (AII). Some experts would combine the intravenous intrapartum/6-week newborn zidovudine regimen with single-dose intrapartum/newborn nevirapine (CIII).***
- ***If single-dose intrapartum/newborn nevirapine is given, an antiretroviral "tail" should be administered to reduce development of nevirapine resistance (AII).***

Table 7 shows dosing for intravenous intrapartum zidovudine given in continuous infusion during labor and neonatal zidovudine dosing; Table 8 shows intrapartum and neonatal dosing for additional drugs to be considered in certain situations as delineated below.

Women Who Have Received Antepartum Antiretroviral Drugs

Use of Intravenous Zidovudine during Labor

The PACTG 076 results and subsequent epidemiologic studies have proven the efficacy of the three-part zidovudine chemoprophylaxis regimen alone or in combination with other antiretroviral agents. The PACTG 076 zidovudine regimen includes a continuous intravenous infusion of zidovudine during labor (initial loading dose of 2 mg/kg intravenously over 1 hour, followed by continuous infusion of 1 mg/kg/hour until delivery). Therefore, intravenous zidovudine during the intrapartum period should be discussed with and recommended to all HIV-infected pregnant women. For a scheduled cesarean delivery, intravenous zidovudine should begin 3 hours before surgery, according to standard dosing recommendations. Women receiving fixed-dose combination regimens that include zidovudine (e.g., the zidovudine/lamivudine combination) should have zidovudine administered intravenously during labor while other antiretroviral components are continued orally (e.g., if a woman is receiving zidovudine/lamivudine during pregnancy, zidovudine should be given intravenously and lamivudine should be given orally during labor).

If known or suspected zidovudine resistance or toxicity has precluded antenatal use of zidovudine, intrapartum zidovudine according to the PACTG 076 protocol should still be recommended unless a woman has a documented history of hypersensitivity. This intrapartum use of the drug is recommended due to the unique characteristics of zidovudine and its proven record in reducing perinatal transmission (see **Management of Antiretroviral Drug Resistance during Pregnancy**). There is a pharmacologic antagonism between zidovudine and stavudine, and therefore these drugs should not be coadministered during labor. Women who are receiving an antepartum stavudine-containing regimen should discontinue stavudine during labor while intravenous zidovudine is being administered, with other components of the regimen continued orally.

Continuation of Antenatal Antiretroviral Drugs during Labor and Postpartum

Women who are receiving an antepartum combination antiretroviral treatment regimen should continue this regimen on schedule as much as possible during the intrapartum period to provide maximal virologic effect and to minimize the chance of development of drug resistance. When cesarean delivery is planned, oral medications may be continued preoperatively with sips of water. Medications requiring food ingestion for absorption could be taken with liquid dietary supplements, contingent on consultation with the attending anesthesiologist in the preoperative period. If maternal antiretroviral therapy must be interrupted temporarily (i.e., for less than 24 hours) in the peripartum period, all drugs (except for intrapartum intravenous zidovudine) should be stopped and reinstituted simultaneously to minimize the chance of resistance developing.

Women Who Have Received Antepartum Antiretroviral Drugs but Have Suboptimal Viral Suppression near Delivery

Women who have received antiretroviral therapy may not achieve complete viral suppression by the time of delivery due to factors such as poor adherence, viral resistance, or late entry into care. Regardless of the reason, all women who have HIV RNA levels >1,000 copies/mL near the time of delivery should be offered a scheduled cesarean delivery at 38 weeks, which may significantly reduce the risk of transmission (see **Transmission and Mode of Delivery**). The addition of single-dose nevirapine during labor has not been shown to reduce perinatal transmission of HIV in this group of women. The PACTG 316 study, conducted in women in the United States, Europe, Brazil, and the Bahamas who were receiving antiretroviral drugs during pregnancy (primarily combination therapy), showed that the addition of single-dose nevirapine did not reduce the risk of mother-to-child transmission of HIV even in the setting of maternal viremia but was associated with the development of nevirapine resistance in 15% of women with detectable HIV RNA postpartum *[1-2]*. However, the number of women with detectable HIV RNA at delivery, and especially with HIV RNA greater than

10,000 copies/mL, was small and may have been insufficient to allow assessment of a possible benefit of single-dose nevirapine in this subgroup. Given the risk of development of resistance and the lack of data to suggest added efficacy, addition of single-dose nevirapine when a woman has received antepartum drugs is generally not recommended. However, single-dose nevirapine use may be considered in special circumstances, such as in women with high HIV RNA levels at or near the time of delivery, especially if delivery is vaginal rather than a scheduled cesarean delivery. If single-dose nevirapine is administered, the use of maternal postpartum zidovudine/lamivudine for at least 7 days is suggested to prevent the development of nevirapine resistance (see **Choice of Intrapartum/Postpartum Antiretroviral Regimen for Women without Antepartum Antiretroviral Therapy**).

Women Who Have Not Received Antepartum Antiretroviral Drugs

Women Who Present in Labor with No Documentation of HIV Status

Any woman without documented HIV status at the time of labor should be screened with rapid HIV testing unless she declines (opt-out screening). Rapid HIV testing is also recommended for women presenting in labor who tested negative for HIV in early pregnancy but are at increased risk of HIV infection and were not retested in the third trimester *[3]*. Factors increasing risk of infection may include diagnosis of an STD, illicit drug use or exchange of sex for money or drugs, multiple sexual partners during pregnancy, a sexual partner at risk of HIV infection, signs/symptoms of acute HIV infection, or living in a region with an elevated incidence of HIV in women of childbearing age without a repeat HIV test in the third trimester *[3]*.

Rapid HIV antibody testing should be available on a 24-hour basis at all facilities with a maternity service and/or neonatal intensive care unit. Statutes and regulations regarding rapid testing vary from state to state; see **http://www.nccc.ucsf.edu/consultation_library/state_hiv_testing_laws** for a review of state HIV testing laws. Current information on rapid testing should also be available at all facilities with a maternity service and/or neonatal intensive care unit.

A woman with a positive rapid antibody test should be presumed to be infected until standard HIV antibody confirmatory testing clarifies her infection. Along with confirmatory HIV antibody testing, the woman should have appropriate assessments (e.g., CD4 count and HIV RNA copy number) as soon as possible to determine maternal health status and whether antiretroviral therapy is recommended for her own health. Arrangements for establishing HIV care and providing ongoing psychosocial support after discharge should also be provided. All women with a positive rapid HIV test in labor should have intravenous zidovudine started immediately to prevent perinatal transmission of HIV, as discussed below.

Choice of Intrapartum/Postpartum Antiretroviral Regimen for Women without Antepartum Antiretroviral Therapy

All HIV-infected women who have not received antepartum antiretroviral therapy should have intravenous zidovudine started immediately to prevent perinatal transmission of HIV (see **Table 7** for dosing information). Although intrapartum/neonatal antiretroviral medications will not prevent perinatal transmission that occurs before labor, most transmission occurs near to or during labor and delivery. Pre-exposure prophylaxis for the fetus can be provided by giving the mother a drug that rapidly crosses the placenta to produce systemic antiretroviral drug levels in the fetus during intensive exposure to HIV in maternal genital secretions and blood during birth. In general, zidovudine and other NRTI drugs as well as NNRTI drugs cross the placenta well, although PI drugs do not (see **Table 4**).

Epidemiologic data indicate that intravenous maternal intrapartum zidovudine followed by oral zidovudine for 6 weeks for the infant significantly reduces transmission compared to no treatment *[4]*.

In a New York State cohort study, transmission rates were 10% with intrapartum and neonatal zidovudine compared with 27% without zidovudine, a 62% reduction in risk *[4]*. The PETRA study demonstrated that intrapartum prophylaxis alone, without an infant post-exposure prophylaxis component, is not effective in reducing perinatal transmission *[5]*.

Whether the addition of other antiretroviral drugs to the intravenous intrapartum/newborn zidovudine regimen when no maternal antepartum drugs have been received increases efficacy in preventing perinatal transmission has not been directly studied. Several intrapartum/neonatal prophylaxis regimens have been found to be effective in international studies. These include oral zidovudine/lamivudine during labor followed by 1 week of oral zidovudine/lamivudine to the infant and single-dose intrapartum/newborn nevirapine *[5-6]*. However, none of these regimens has been compared to intravenous zidovudine combined with 6 weeks of infant zidovudine prophylaxis.

An ongoing study in the United States, Brazil, Argentina, and South Africa is assessing whether adding drugs to the intravenous intrapartum/newborn zidovudine regimen will enhance efficacy in reducing perinatal transmission. In the absence of data, some experts feel additional drugs may be warranted. One option is to add the single-dose intrapartum/newborn nevirapine regimen to the intravenous/6-week infant zidovudine regimen. Although single-dose nevirapine did not provide additional efficacy when added to antepartum combination antiretroviral regimens in PACTG 316, in this situation, no maternal antepartum therapy has been given. Theoretical advantages of combining the zidovudine and nevirapine intrapartum/neonatal regimens include the known short-term safety of each regimen alone, excellent transplacental passage of both drugs, greater antiviral activity of nevirapine compared to zidovudine, as well as the activity of nevirapine against extracellular and intracellular virus *[7-8]*, and the known synergy of zidovudine and nevirapine in inhibiting HIV replication *in vitro [9]*.

However, single-dose nevirapine is associated with the development of nevirapine -resistant virus (see **Incidence of Antiretroviral Resistance with Perinatal Prophylactic Regimens**) *[2, 10-12]*. Studies have shown that nevirapine resistance after intrapartum administration of single-dose nevirapine can be substantially reduced (but not eliminated) by using a short postpartum course of antiretroviral agents from alternate classes (a “tail”). There is no current consensus about the exact duration or composition of the antiretroviral tail. Several trials in Africa have found 3–7 days of maternal/infant postpartum zidovudine/lamivudine to be effective *[13-15]* (See **Table 8** for dosing information.) Development of resistance to zidovudine or lamivudine given for a short period in this setting is rare *[16-17]*. More recent studies have found that 7 days of tenofovir/emtricitabine *[18]*, 7 days of zidovudine/didanosine/lopinavir-ritonavir *[19]*, and 30 days of zidovudine/didanosine or zidovudine/didanosine/lopinavir-ritonavir *[19-20]* all appear to be effective at reducing the development of nevirapine resistance. In the United States the use of maternal postpartum zidovudine/lamivudine for at least 7 days is suggested as a reasonable tail after intrapartum single-dose nevirapine use (see **Neonatal Postnatal Care** section for discussion of infant regimens). Other tail options may also be considered.

Table 7. Intrapartum Maternal and Neonatal Zidovudine (ZDV) Dosing for Prevention of Mother-to-Child Transmission of HIV

Maternal Intrapartum		
Drug	**Dosing**	**Duration**
ZDV	2 mg per kg body weight intravenously over 1 hour, followed by continuous infusion of 1 mg per kg body weight per hour	Onset of labor until delivery of infant
Neonatal		
Drug	**Dosing**	**Duration**
ZDV	>35 weeks gestation: 2 mg per kg body weight per dose given orally [1, 2] (or 1.5 mg per kg body weight per dose given intravenously) started within 6–12 hours of delivery, then every 6 hours	Birth to 6 weeks
ZDV	<35 to >30 weeks gestation: 2 mg per kg body weight per dose given orally (or 1.5 mg per kg body weight per dose given intravenously) started within 6–12 hours of delivery, then every 12 hours, advanced to every 8 hours at 2 weeks of age	Birth to 6 weeks
ZDV	<30 weeks gestation: 2 mg per kg body weight per dose given orally (or 1.5 mg/kg/dose given intravenously) started within 6–12 hours of delivery, then every 12 hours, advanced to every 8 hours at 4 weeks of age	Birth to 6 weeks

[1] Zidovudine dosing of 4 mg per kg body weight per dose given every 12 hours has been used for infant prophylaxis in some international perinatal studies. Although there are no definitive data to show equivalent pharmacokinetic parameters or efficacy in preventing transmission, a regimen of zidovudine 4 mg per kg body weight per dose given orally twice daily instead of 2 mg per kg body weight per dose given orally 4 times daily may be considered when there are concerns about adherence to drug administration to the infant.

[2] A simplified zidovudine dosing regimen has been developed for use in low resource settings. This regimen consists of 10 mg orally twice daily for infants weighing less than 2.5 kg at birth and 15 mg twice daily for infants weighing more than 2.5 kg at birth. See discussion in **Neonatal Postnatal Care: Infant Antiretroviral Prophylaxis**. This regimen could be considered for infants in higher resource settings born after 35 weeks gestation if simplicity in zidovudine dosing and administration is of prime importance.

Table 8. Intrapartum Maternal and Neonatal Dosing for Additional Antiretroviral Drugs to be Considered Only in Selected Circumstances

*(See **Special Considerations Regarding the Use of Antiretroviral Drugs by HIV-Infected Pregnant Women and their Infants** and **Antiretroviral Drug Resistance and Resistance Testing in Pregnancy** for further discussion.)*

Maternal Intrapartum/Postpartum		
Drug	**Dosing**	**Duration**
NVP (as single dose intrapartum)[1]	200 mg given orally as single dose	Single dose at onset of labor
ZDV + 3TC (given with single dose NVP as "tail" to reduce NVP resistance)	ZDV: intravenously intrapartum as per **Table 7**, then after delivery 300 mg orally twice daily 3TC: 150 mg orally twice daily starting at onset of labor	Through 1 week postpartum
Neonatal		
Drug	**Dosing**	**Duration**
NVP (as single dose)[2]	2 mg per kg body weight given orally as single dose	Single dose between birth and 72 hours of age. If maternal dose is given ≤ 2 hours before delivery or not received, infant dose should be administered as soon as possible following birth.[3]
ZDV + 3TC (given with single dose NVP as "tail" to reduce NVP resistance)	ZDV: neonatal dosing as per **Table 5** 3TC: 2 mg per kg body weight given orally twice daily	ZDV: Birth to 6 weeks 3TC: Birth to 1 week

Key to Abbreviations: NVP = nevirapine, ZDV = zidovudine, 3TC = lamivudine

[1] Given *in addition* to intravenous intrapartum ZDV; if intrapartum single-dose NVP is given to mother, administration of intrapartum oral 3TC followed by administration of ZDV and 3TC for at least 7 days postpartum to reduce development of NVP-resistant virus is recommended.

[2] Given *in addition* to 6 weeks of infant ZDV; addition of at least 7 days of 3TC may be considered to reduce development of NVP-resistant virus.

[3] Some experts recommend a second NVP dose at 48–72 hours of life to babies born in this circumstance.

TRANSMISSION AND MODE OF DELIVERY

Panel's Recommendations:

- ***Scheduled cesarean delivery at 38 weeks gestation is recommended for women with HIV RNA levels >1,000 copies/mL near the time of delivery (whether receiving or not receiving antepartum antiretroviral drugs) and for women with unknown HIV RNA levels near the time of delivery (AII).***
- ***It is not clear whether cesarean delivery after rupture of membranes or onset of labor provides benefit in preventing perinatal transmission. Management of women originally scheduled for cesarean delivery who present with ruptured membranes or in labor must be individualized based on duration of rupture, progress of labor, plasma HIV RNA level, current antiretroviral therapy, and other clinical factors (BII).***
- ***Data are insufficient to evaluate the potential benefit of cesarean delivery for prevention of perinatal transmission in pregnant women receiving combination antiretroviral drugs with plasma HIV RNA levels <1,000 copies/mL near the time of delivery. Given the low rate of transmission among this group, it is unclear whether scheduled cesarean delivery would confer additional benefit in reduction of transmission. Decisions should be individualized based on discussion between the obstetrician and the mother (BII).***
- ***Among HIV-infected women, use of prophylactic antibiotics at the time of cesarean delivery is recommended (AII).***
- ***Women should be informed of the risks associated with cesarean delivery; the risk to the woman should be balanced with potential benefits expected for the neonate (AIII).***

Basis for Current Recommendations

Scheduled cesarean delivery, defined as cesarean delivery performed before the onset of labor and before ruptured membranes, is recommended for women with HIV RNA levels >1,000 copies/mL near the time of delivery and for women with unknown HIV RNA levels *[1]*.

This recommendation is based on the findings from a multi-center randomized clinical trial *[2]* and a large individual patient data meta-analysis *[3]*. These two studies were conducted at a time when the majority of women received no antiretroviral medications or zidovudine as a single drug and before the availability of viral load information. However, study results have been extrapolated to make recommendations regarding the mode of delivery in an era when combination antiretroviral therapy during pregnancy is recommended and viral load information is readily available. In the randomized clinical trial, 1.8% of infants born to women randomized to undergo cesarean delivery were HIV infected compared to 10.5% of infants born to women randomized to deliver vaginally ($p<0.001$). When adjusted for antiretroviral use in pregnancy (zidovudine alone), scheduled cesarean delivery lowered the risk of HIV transmission by 80%, although the results were no longer statistically significant (OR 0.2, 95% CI 0–1.7). When the data were analyzed by the actual mode of delivery, rather than to what group women were allocated, there was still a protective effect of scheduled cesarean delivery (adjusted odds ratio [OR] 0.3; 95% CI 0.1–0.8) but not with emergency cesarean delivery (adjusted OR 1.0; 95% CI 0.3–3.7) *[2]*. Results from a large meta-analysis of individual patient data from 15 prospective cohort studies also demonstrated a benefit of scheduled cesarean delivery with a 50% reduction in risk *[3]*. Primarily based on these data, the American College of

Obstetricians and Gynecologists (ACOG) has recommended consideration of scheduled cesarean delivery for HIV-infected pregnant women since 1999 *[4]*.

HIV RNA Level of 1,000 copies/mL as a Threshold for Recommendation of Cesarean Delivery

The original ACOG committee opinion was updated in 2000 to include further refinements based on HIV RNA levels *[1]*. Currently, ACOG *[1]* recommends that women with HIV RNA >1,000 copies/mL be counseled regarding the potential benefits of scheduled cesarean delivery. Initially, this threshold of 1,000 copies/mL was based largely on data from the Women and Infants Transmission Study (WITS), a large prospective cohort study that reported no HIV transmission among 57 women with HIV RNA levels <1,000 copies/mL *[5]*. Since that time, newer studies have demonstrated that HIV transmission occurred among infants born to women with low viral loads. In an analysis of 957 women with plasma viral loads of <1,000 copies/mL, cesarean delivery (scheduled or urgent) reduced the risk of HIV transmission when adjusting for potential confounders including receipt of maternal antiretroviral therapy, primarily zidovudine alone as prophylaxis (adjusted OR 0.30; p=0.022) *[6]*. Overall, the transmission rate among women with HIV RNA <1,000 copies/mL receiving antiretroviral therapy was 8 (1%) of 834. In a more recent report from a comprehensive national surveillance system in the United Kingdom and Ireland, 3 (0.1%) of 2,309 and 12 (1.2%) of 1,023 infants born to women with HIV RNA of <50 copies/mL and 50–999 copies/mL, respectively, were HIV infected *[7]*. These later studies document that transmission can occur even at very low HIV RNA levels. However, given the low rate of transmission among this group, it is unclear whether scheduled cesarean delivery confers any additional benefit in reduction of transmission. Therefore, decisions about mode of delivery for women with HIV RNA levels <1,000 copies/mL should be individualized based on discussion between the obstetrician and the mother.

Cesarean Delivery in the HAART Era

In surveillance data from the United Kingdom and Ireland, pregnant women receiving combination antiretroviral drugs regimens (e.g., at least 3 drugs) had transmission rates of about 1%, unadjusted for mode of delivery. Pregnant women with undetectable HIV viral load (< 50 copies/mL) had transmission rates of about 0.1% *[7]*. Given the low transmission rates achievable with use of maternal combination antiretroviral therapy or prophylaxis, the benefit of scheduled cesarean delivery is difficult to evaluate. Both the randomized clinical trial *[2]* and meta-analysis *[3]* documenting the benefits of cesarean delivery included mostly women who were receiving either no antiretrovirals or zidovudine only. However, other data partially address this issue. In a report from the European Collaborative Study that included data from 4,525 women, the overall transmission rate among the subset of women on a combination antiretroviral regimen was 11(1.2%) of 918 *[8]*. Among the subset of 560 women with undetectable HIV RNA levels (≤ 50 to ≤200 copies/mL, depending on site), scheduled cesarean delivery was associated with a significant reduction in perinatal transmission in univariate analysis (OR 0.07, 95% CI 0.02–0.31, p=0.0004). However, after adjustment for antiretroviral therapy (none vs. any), the effect was no longer significant (adjusted OR 0.52, 95% CI 0.14–2.03, p=0.359). Similarly, data from a European surveillance study did not demonstrate a statistically significant difference in transmission rates between scheduled cesarean delivery and planned vaginal delivery (adjusted OR 1.24; 95% CI 0.34–4.5) among women on combinational antiretroviral therapy or prophylaxis *[7]*. The transmission rate among all women who received at least 14 days of antiretroviral therapy was 40 (0.8%) of 4,864, regardless of mode of delivery. Therefore, it is not clear whether there is any benefit from scheduled cesarean delivery among women who have been receiving combination antiretroviral therapy for several weeks.

Women Presenting Late in Pregnancy

HIV-infected women who present in late pregnancy and are not receiving antiretroviral drugs may not have HIV RNA results available before delivery. Without current therapy, HIV RNA levels are unlikely to be <1,000 copies/mL at baseline. Even if combination antiretroviral therapy were begun immediately, reduction in plasma HIV RNA to undetectable levels usually takes several weeks, depending on the baseline RNA level *[9]*. In this instance, scheduled cesarean delivery is likely to provide additional benefit in reducing risk of perinatal transmission of HIV for women with unknown HIV RNA levels near the time of delivery.

Timing of Scheduled Cesarean Delivery

In general, for women without HIV infection, ACOG recommends that scheduled cesarean delivery not be performed before 39 weeks gestation due to the risk of iatrogenic prematurity *[10-11]*. However, in cases of cesarean delivery performed to prevent HIV transmission, ACOG recommends scheduling cesarean delivery at 38 weeks gestation in order to decrease the likelihood of onset of labor or rupture of membranes before delivery *[1]*. Among all women undergoing repeat cesarean delivery, the risk of any neonatal adverse event, which includes neonatal death, respiratory complications, hypoglycemia, newborn sepsis, or admission to the neonatal intensive care unit, is 15.3% at 37 weeks, 11.0% at 38 weeks, and 8.0% at 39 weeks *[11]*. Clinicians should recognize that newborn complications may be increased in planned early term births <39 weeks gestation. However, for HIV-infected women the benefits of decreasing HIV transmission by planned delivery at 38 weeks are generally thought to outweigh the risks. Furthermore, gestational age should be determined by last menstrual period and ultrasonography because amniocentesis to document lung maturity should be avoided when possible *[1]*.

Risk of Maternal Complications

Because maternal infectious morbidity is increased with cesarean delivery even among women without HIV infection, use of peri-operative antimicrobial prophylaxis is recommended for all women undergoing cesarean delivery. Most studies have demonstrated that HIV-infected women have increased rates of postoperative complications, mostly infectious, compared to HIV-uninfected women and that the risk of complications is related to the degree of immunosuppression *[12-17]*. Furthermore, a Cochrane review of six studies of HIV-infected women concluded that urgent cesarean delivery was associated with the highest risk of postpartum morbidity, that scheduled cesarean delivery was intermediate in risk, and that vaginal delivery had the lowest risk of morbidity *[18]*. Complication rates in most studies *[2, 19-23]* were within the range reported in populations of HIV-uninfected women with similar risk factors and were not of sufficient frequency or severity to outweigh the potential benefit of reduced transmission. Therefore, HIV-infected women should be counseled regarding the increased risks and potential benefits associated with cesarean delivery based on their HIV RNA levels and current antiretroviral therapy.

Management of Women Who Present in Early Labor or With Ruptured Membranes

Few data are available to address the question of whether performing cesarean delivery after the onset of labor or membrane rupture may decrease the risk of perinatal transmission of HIV. Most studies have shown the risk of transmission with cesarean delivery done after labor and membrane rupture for obstetric indications to be similar to that with vaginal delivery. In one study, the HIV transmission rate among women undergoing emergency cesarean delivery was similar to women delivering vaginally (1.6% vs. 1.9%, respectively) *[7]*. A meta-analysis of women mostly on zidovudine as a single drug or no antiretroviral therapy demonstrated a 2% increased transmission risk for every additional hour of ruptured membranes *[24]*. However, it is not clear how soon after the onset of labor or the rupture of membranes the benefit of cesarean delivery is lost *[25]*. Therefore, the management of women

originally scheduled for cesarean delivery who present with ruptured membranes or in labor must be individualized based on clinical factors such as duration of rupture, progress of labor, plasma RNA level, and current antiretroviral therapy or prophylaxis status. When membrane rupture occurs prior to 37 weeks gestation, decisions about delivery should be based on gestational age, HIV RNA level, current antiretroviral regimen, and evidence of acute infection (e.g., chorioamnionitis); consultation with an expert is recommended. The antiretroviral drug regimen should be continued and consideration given to initiating intravenous zidovudine if imminent delivery seems possible. There are no data to suggest that use of steroids to accelerate fetal lung maturity should be altered among HIV-infected women.

Table 9 provides a summary of recommendations regarding mode of delivery for different clinical scenarios.

Table 9. Clinical Scenarios and Recommendations Regarding Mode of Delivery to Reduce Perinatal Transmission of HIV

Clinical Scenario	Recommendations
HIV-infected woman presenting in late pregnancy (after about 36 weeks gestation), known to be HIV-infected but not receiving antiretroviral therapy, and who has HIV RNA level and CD4 count pending but unlikely to be available before delivery.	• The woman should be started on antiretroviral therapy as per **Table 6**. • The woman should be counseled that scheduled cesarean delivery is likely to reduce the risk of transmission to her infant. She should also be informed of the increased risks to her of cesarean delivery, including increased rates of postoperative infection, anesthesia risks, and other surgical risks. • If cesarean delivery is chosen, the procedure should be scheduled at 38 weeks gestation based on the best available clinical information. • When scheduled cesarean delivery is performed, the woman should receive continuous intravenous zidovudine infusion beginning 3 hours before surgery. • Use of prophylactic antibiotics at the time of cesarean delivery is generally recommended. • Options for continuing or initiating combination antiretroviral therapy after delivery should be discussed with the woman as soon as her viral load and CD4 count results are available. • The infant should receive 6 weeks of zidovudine after birth (see **Table 6**).
HIV-infected woman who initiated prenatal care early in the third trimester, is receiving a combination antiretroviral regimen, and has an initial virologic response but has HIV RNA levels that remain substantially greater than 1,000 copies/mL at 36 weeks gestation.	• The current combination antiretroviral regimen should be continued because the HIV RNA level is dropping appropriately. • The woman should be counseled that although she is responding to the antiretroviral therapy, it is unlikely that her HIV RNA level will fall below 1,000 copies/mL before delivery. Therefore, scheduled cesarean delivery may provide additional benefit in preventing intrapartum transmission of HIV. She should also be informed of the increased risks to her of cesarean delivery, including risks related to anesthesia and surgery and increased rates of postoperative infection. • If the woman chooses scheduled cesarean delivery, the procedure should be performed at 38 weeks gestation as determined by last menstrual period and ultrasonography. Intravenous zidovudine should be started at least 3 hours before surgery. • Other antiretroviral medications should be continued on schedule as much as possible before and after surgery. • Use of prophylactic antibiotics at the time of cesarean delivery is generally recommended. • The importance of adhering to therapy after delivery for the woman's health should be emphasized. • The infant should receive 6 weeks of zidovudine after birth (see **Table 6**).
HIV-infected woman on a combination antiretroviral regimen with an undetectable HIV RNA level at 36 weeks gestation.	• The woman should be counseled that her risk of perinatal transmission of HIV with a persistently undetectable HIV RNA level is low, probably 1% or less, even with vaginal delivery. There is currently no evidence that performing a scheduled cesarean delivery will lower her risk further. • Cesarean delivery has an increased risk of complications for the woman compared to vaginal delivery, and these risks must be balanced against the uncertain benefit of cesarean delivery in this case. • The infant should receive 6 weeks of zidovudine after birth (see **Table 6**).

Clinical Scenario	Recommendations
HIV-infected woman who has elected scheduled cesarean delivery but presents after rupture of membranes at >37 weeks gestation.	• Intravenous zidovudine should be started immediately. • Decision regarding mode of delivery should be individualized and based on clinical factors such as duration of rupture, anticipated progress of labor, plasma RNA level, and current antiretroviral therapy. • If the decision is made to proceed with vaginal delivery, some clinicians may consider administration of oxytocin, if clinically appropriate, in order to expedite delivery. Scalp electrodes and other invasive monitoring and operative delivery should be avoided if possible. • If the decision is made to proceed with cesarean delivery, administration of the loading dose of intravenous zidovudine should be completed prior to cesarean delivery. • The infant should receive 6 weeks of zidovudine after birth (see **Table 6**).

OTHER INTRAPARTUM MANAGEMENT CONSIDERATIONS

Panel's Recommendations:

- ***Artificial rupture of membranes should generally be avoided because of a small but potential increased risk of transmission (BIII).***
- ***Routine use of fetal scalp electrodes for fetal monitoring should be avoided in the setting of maternal HIV infection (BIII).***
- ***Operative delivery with forceps or the vacuum extractor and episiotomy should be performed only in select circumstances (BIII).***
- ***When uterine atony results in excessive postpartum bleeding in women receiving a protease inhibitor or efavirenz, methergine should not be used unless alternative treatments for postpartum hemorrhage are not available and if the need for pharmacologic treatment outweighs the risks. If used, methergine should be administered in the lowest effective dose for the shortest duration possible (BIII).***

If spontaneous rupture of membranes occurs before or early during the course of labor, interventions to decrease the interval to delivery, such as administration of oxytocin, may be considered. For women who present in labor and the decision is made to proceed with vaginal delivery despite detectable viral load, artificial rupture of membranes should be avoided and employed only for a clear obstetric indication. For women with nondetectable viral load and planned vaginal delivery, data are limited, but artificial rupture of membranes should generally still be avoided and be performed only for clear obstetrical indications in order to avoid the small but potential increased risk of HIV transmission.

Obstetric procedures increasing the risk of fetal exposure to maternal blood, such as invasive fetal monitoring, have been implicated in increasing vertical transmission rates by some, but not all, investigators *[1-4]*. Although data are limited, the routine use of fetal scalp electrodes in labor should be avoided in the setting of maternal HIV infection because of the potential risk of disruption of fetal skin.

Operative vaginal delivery with forceps or the vacuum extractor and/or use of episiotomy theoretically may increase the risk of transmission but should not be delayed if there are clear obstetric indications *[2, 4]*.

Postpartum Hemorrhage, Antiretroviral Drugs, and Methergine Use

Women experiencing postpartum hemorrhage due to uterine atony are often managed with oral or parenteral methergine or other ergot alkaloids as a first-line agent. However, methergine should not be coadministered with drugs that are potent CYP3A4 enzyme inhibitors, including protease inhibitors. The concomitant use of ergotamines (e.g., methergine) and protease inhibitors has been associated with exaggerated vasoconstrictive responses. When uterine atony results in excessive postpartum bleeding in women receiving protease inhibitors or efavirenz as a component of an antiretroviral regimen, methergine should not be used unless alternative treatments (e.g., prostaglandin F 2 alpha, misoprostol, or oxytocin) are not available. If there are no alternative medications available and the need for pharmacologic treatment outweighs the risks, methergine should be used in as low a dosage and for as short a duration as possible. When other antiretroviral agents are used that are CYP3A4 inducers, there is the potential for decreased methergine levels and inadequate treatment effect; therefore, additional uterotonic agents may be needed.

Postpartum Care (Updated May 24, 2010)

POSTPARTUM FOLLOW-UP OF HIV-INFECTED WOMEN

Panel's Recommendations:

• The decision to continue antiretroviral therapy after delivery should be based on the nadir CD4 count, clinical symptoms/disease stage, presence of other indications for antiretroviral therapy, and patient and provider preference (AI).

• The immediate postpartum period poses unique challenges for adherence; new or continued supportive services should be assured prior to hospital discharge (AII).

• Women with a positive rapid HIV antibody test during labor require comprehensive follow-up, including confirmation of HIV infection and, if infection is confirmed, a full health assessment including evaluation for associated medical conditions, counseling related to newly diagnosed HIV infection, and assessment of need for antiretroviral therapy and opportunistic infection prophylaxis (AII).

• Breastfeeding is not recommended for HIV-infected women in the United States (AI).

• Contraceptive counseling should be included as a critical aspect of postpartum care (AIII).

Comprehensive care and support services are particularly important for women with HIV infection and their families, who often face multiple medical and social challenges. Components of comprehensive care include the following medical and supportive care services as needed:

- primary, gynecologic/obstetric, and HIV specialty care for the HIV-infected woman;
- pediatric care for her infant;
- family planning services;
- mental health services;
- substance abuse treatment;
- support services; and
- coordination of care through case management for the woman, her child(ren), and other family members.

Support services should be tailored to the individual woman's needs and may include case management, child care, respite care, assistance with basic life needs (e.g., housing, food, transportation), peer counseling, and legal and advocacy services. Ideally, this care should begin before pregnancy and should be continued throughout pregnancy and the postpartum period.

Maternal medical services during the postpartum period must be coordinated between obstetric care providers and HIV specialists. It is especially critical to ensure continuity of antiretroviral treatment when such treatment is required for the woman's health. The decision whether to continue antiretroviral therapy after delivery will depend on the woman's nadir CD4 count; clinical symptoms/disease stage; presence of other indications for antiretroviral therapy, such as chronic hepatitis B; and patient and provider preference. Ideally, a discussion of these factors should occur well before delivery.

Concerns have been raised about adherence to antiretroviral regimens during the postpartum period. Women should be counseled that the physical and psychological changes of the postpartum period, as well as the stresses and demands of caring for a new baby, might make adherence more difficult and that additional support may be needed to maintain good adherence during this period *[1-3]*. The health care provider should

be vigilant for signs of depression and illicit drug or alcohol use, which may require assessment and treatment and which may interfere with adherence. Poor adherence has been shown to be associated with virologic failure, development of resistance, and decreased long-term effectiveness of antiretroviral therapy *[4-6]*. Efforts to maintain adequate adherence during the postpartum period might prolong the effectiveness of therapy. See the section on *Adherence* in the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***.

Women with nadir CD4 counts less than the currently recommended threshold for institution of antiretroviral therapy *[7]* and/or symptomatic HIV infection should be encouraged to continue their antiretroviral regimens postpartum with no interruption. For women who began antiretroviral drugs for prophylaxis of transmission with a nadir CD4+ cell count greater than that currently recommended for treatment *[7]*, the decision of whether to continue therapy after delivery should be made in consultation with the HIV provider, taking into account current and nadir CD4+ lymphocyte counts and trajectory, HIV RNA levels, and patient preference.

For women whose antepartum regimen included an NNRTI and who plan to stop antiretroviral prophylaxis after delivery, consideration should be given to stopping the NNRTI and continuing the other antiretroviral drugs or switching from an NNRTI to a PI prior to interruption and continuing the PI with the other antiretroviral drugs for a period of time before electively stopping. The optimal interval between stopping an NNRTI and the other antiretroviral drugs is not known; at least 7 days is recommended. Given the potential of prolonged detectable NNRTI concentrations for more than 3 weeks in patients receiving efavirenz-based therapy, some experts recommend continuing the other antiretroviral agents or substituting a PI plus two other agents for up to 30 days. (See **Stopping Antiretroviral Therapy during Pregnancy** and **Prevention of Antiretroviral Drug Resistance**).

Among women with indications for continued antiretroviral therapy postpartum, planned interruption of antiretroviral therapy for several weeks or months has not been studied prospectively and cannot be recommended. However, women may be at increased risk of decreased adherence during the postpartum period. Intermittent adherence increases the risk of developing HIV resistance, so every effort should be made to maximize adherence. Simplification of an antiretroviral regimen (for example, to once-daily medications) could be considered. If a woman is unable to adhere to her regimen, it may be preferable to temporarily interrupt antiretroviral therapy while she works with her provider on strategies to improve adherence.

Data on follow-up of women from PACTG 076 who received antepartum and intrapartum zidovudine prophylaxis with discontinuation of the drug after delivery (median follow-up 4 years) demonstrated no difference in clinical, immunologic, virologic, and resistance status compared to women who received placebo *[8]*. Among women with CD4 cell counts >350 cells/mm^3 followed in the Women and Infants Transmission Study (WITS) cohort, there were no significant differences in CD4 count or disease progression among those who did or did not continue antiretroviral treatment after delivery *[9]*. However, for women receiving current combination antiretroviral prophylaxis regimens with no indication to continue antiretroviral therapy postpartum, the effect of limited-duration, fully suppressive antiretroviral prophylaxis in pregnancy on future treatment efficacy is unknown, and further research is needed. Such women may eventually require antiretroviral therapy again in the context of subsequent pregnancies or for advancing HIV disease.

Women with a positive rapid HIV antibody test during labor or at delivery require comprehensive medical assessment, counseling, and follow-up. Confirmatory HIV antibody testing should be performed as soon as possible after an initial positive rapid test to minimize the delay for definitive diagnosis *[10]*. Women with a positive rapid HIV antibody test should not breastfeed unless the confirmatory HIV test is negative. Women with a new HIV diagnosis postpartum should receive the same thorough evaluation as other newly identified infected patients, including consideration of antiretroviral therapy and opportunistic infection prophylaxis as indicated. Her other children and partner(s) should be referred for HIV testing.

In the United States and other parts of the world where replacement feeding is affordable, feasible, acceptable, sustainable, and safe, breastfeeding by HIV-infected women (including those receiving antiretroviral drugs) is

not recommended. Postpartum HIV transmission via breast milk is well documented and the risk of transmission is related to a variety of factors, including maternal health status and breast milk cell-free and cell-associated viral load *[11]*. There are no safe methods to treat breast milk that will completely eliminate the risk of HIV transmission associated with breastfeeding. Data are limited regarding the penetration of antiretroviral drugs into breast milk. The available data indicate that there is differential penetration of drugs into milk, with some drugs having high levels while others may have low or undetectable levels in breast milk, which raises concerns regarding both infant toxicity and selection of drug-resistant virus within breast milk *[12-13]*. Three studies have found multi-class drug resistance in breastfeeding infants who have become infected despite maternal triple antiretroviral drug prophylaxis *[14-16]*. Additionally, drug levels in the neonate from ingested breast milk may be subtherapeutic and cannot be relied on to interrupt transmission of HIV via breast milk.

Contraceptive counseling is a critical aspect of postpartum care. Although condoms are universally recommended for prevention of STD/HIV transmission, the unintended pregnancy rate even with consistent condom use alone is estimated at 10%–15% annually. Women should be educated about the risk of unintended pregnancy when condoms are the sole contraceptive method used. If another pregnancy is not desired in the near future and/or if the antiretroviral regimen contains potentially teratogenic agents such as efavirenz, women should be offered dual-method contraception *[17]*. Reversible options include intrauterine devices, which have been shown to be safe and effective in HIV-infected women *[18]*, and hormonal methods. Emergency contraception should not be recommended for routine use as a form of contraception but should be provided for use within 72 hours after an episode of unprotected intercourse or broken condom for women declining additional contraception.

Drug interactions have been documented between oral contraceptives and many antiretrovirals (see the ***Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents***, Tables 13, 14a, and 14b) *[7]*. These interactions do not necessarily rule out the use of hormonal contraceptive methods because there is no clear evidence of an effect on contraceptive or antiretroviral efficacy or toxicity. However, amprenavir/fosamprenavir levels are significantly lowered by oral contraceptives and co-administration is not recommended; it is not known if low-dose ritonavir boosting raises amprenavir levels sufficiently to allow co-administration. Depot medroxyprogesterone acetate (Depo-Provera, DMPA) pharmacokinetics are not significantly affected by nevirapine, efavirenz, or nelfinavir, and levels of these drugs were not significantly altered by DMPA *[19]*. Potential interactions between antiretroviral agents and the transdermal contraceptive patch, vaginal ring, and other implantable forms of contraception have not yet been defined. Permanent sterilization is an appropriate option only for those women who are certain they do not desire future childbearing. Advance counseling and discussion about sterilization is strongly encouraged in order to enable the woman to make a well-informed choice.

The postpartum period provides an opportunity to review and optimize women's health care; this should include cervical cancer screening and routine immunizations. This period also provides an opportunity to assess the need for behavioral health interventions; this should include mental health screening, including an assessment for signs of postpartum depression, and substance abuse treatment as indicated. Providers should also re-emphasize the importance of safer sex practices.

Neonatal Postnatal Care (Updated May 24, 2010)

INFANTS BORN TO MOTHERS WITH UNKNOWN HIV INFECTION STATUS

Panel's Recommendations:

- ***For infants born to mothers with unknown HIV status, rapid HIV antibody testing of the mother and/or infant is recommended as soon as possible after birth, with initiation of infant antiretroviral prophylaxis immediately if the rapid test is positive (AII).***
- ***If the rapid HIV antibody test is positive, standard antibody confirmatory testing (e.g., Western blot) should be performed on the mother (or her infant) as soon as possible. If the confirmatory test is negative, antiretroviral prophylaxis can be discontinued (AIII).***
- ***If the HIV antibody confirmatory test is positive, a newborn HIV DNA PCR should be obtained (AIII).***
- ***If the newborn HIV DNA PCR is positive, antiretroviral prophylaxis should be discontinued and the infant promptly referred to a pediatric HIV specialist for confirmation of the diagnosis and treatment of HIV infection with standard combination antiretroviral therapy (AI). The HIV-infected infant should also receive chemoprophylaxis against Pneumocystis jirovecci pneumonia (PCP) with oral trimethoprim-sulfamethoxazole according to guidelines (AII).***

If maternal HIV status is unknown and a rapid HIV antibody test was not performed on the mother during labor, rapid HIV antibody testing of the mother and/or infant is recommended as soon as possible after birth, with initiation of antiretroviral prophylaxis for the infant immediately if the rapid test is positive. Rapid HIV antibody testing should be available on a 24-hour basis at all facilities with a maternity service and/or neonatal intensive care or newborn nursery. A positive rapid antibody test on the mother or the infant should be presumed to indicate maternal HIV infection until standard antibody confirmatory testing clarifies maternal status. A standard confirmatory test (e.g., Western blot) should be performed on the mother (or her infant) as soon as possible after the initial positive rapid test *[1]*. A positive HIV antibody test in the infant indicates maternal but not necessarily infant HIV infection. Diagnosing HIV infection in infants <18 months of age requires virologic testing. If the confirmatory test on the mother (or infant) is negative, antiretroviral prophylaxis can be discontinued. If the confirmatory test is positive, an HIV DNA PCR should be obtained urgently from the newborn. If the HIV DNA PCR is positive, antiretroviral prophylaxis should be promptly discontinued and the infant should receive treatment for HIV infection with standard combination antiretroviral therapy according to established Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection developed by The Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children (**http://aidsinfo.nih.gov/contentfiles/PediatricGuidelines.pdf**). In addition, all newly diagnosed HIV-infected infants should receive chemoprophylaxis to prevent *Pneumocystis jirovecii* pneumonia (PCP) with oral trimethoprim-sulfamethoxazole beginning at 4–6 weeks of age *[2]*.

INFANT ANTIRETROVIRAL PROPHYLAXIS

Panel's Recommendations:

- ***The 6-week neonatal component of the zidovudine chemoprophylaxis regimen is recommended for all HIV-exposed neonates to reduce perinatal HIV transmission (AI).***
- ***Zidovudine should be initiated as close to the time of birth as possible, preferably within 6 to 12 hours of delivery (AII).***
- ***The 6-week zidovudine prophylaxis regimen is recommended at gestational age-appropriate doses; zidovudine should be dosed differently for premature infants <35 weeks than for infants ≥35 weeks (see text) (AII).***
- ***In the United States, the use of antiretroviral drugs other than zidovudine cannot be recommended in premature infants due to lack of dosing and safety data (BIII).***
- ***The use of intrapartum/neonatal zidovudine is recommended regardless of maternal zidovudine resistance history (BIII).***
- ***The decision to combine additional drugs with the 6-week zidovudine regimen should be accompanied by consultation with a pediatric HIV specialist and a discussion of the potential risks and benefits of this approach with the mother, preferably before delivery (BIII).***
- ***Some experts consider the use of zidovudine in combination with other antiretroviral drugs in certain situations, although the optimal prophylactic regimen for infants born to women in these circumstances is unknown (CIII).***
- ***Decisions regarding the use of additional drugs for the neonate will depend on the history of maternal past and current antiretroviral drug exposure, maternal HIV RNA level at or near delivery, current and previous maternal resistance testing, and availability of drug formulation and dosing information in the infant. If additional drugs are used, choice of drugs and dosing recommendations should be determined in consultation with a pediatric HIV specialist (CIII).***
- ***The National Perinatal HIV Hotline (1-888-448-8765) provides free clinical consultation on all aspects of perinatal HIV including infant care.***

Zidovudine Dosing

All HIV-exposed infants should receive postpartum antiretroviral drugs to reduce perinatal HIV transmission. The 6-week neonatal zidovudine chemoprophylaxis regimen is recommended for all HIV-exposed infants *[3-4]*. **Table 7** shows dosing for intravenous intrapartum zidovudine given in continuous infusion during labor and neonatal zidovudine dosing. **Table 8** shows intrapartum and neonatal dosing for additional drugs to be considered in certain situations as delineated below.

The recommended dose of zidovudine for post-exposure prophylaxis in full-term neonates is 2 mg/kg body weight orally every 6 hours for the first 6 weeks of life, starting as close to the time of birth as possible, preferably within 6 to 12 hours of delivery. If given intravenously, the dose is 1.5 mg/kg body weight every 6 hours. However, some international studies have used an oral infant zidovudine dose of 4 mg/kg body weight twice daily for prophylaxis *[5-9]*. Zidovudine is now approved for two or three times a day dosing when used for treatment of HIV-infected children aged 4 weeks or older and weighing 4 kg or greater. Although there are no definitive data to show pharmacokinetic equivalence of giving double the standard dose at a longer interval when using zidovudine for prophylaxis or whether such dosing has equivalent efficacy in reducing perinatal transmission, a regimen of dosing twice instead of four times daily may increase adherence to the regimen and could be considered when there are concerns about adherence to drug administration to the infant. However, there is inadequate hematologic safety data with administration of double the standard dose of zidovudine

twice daily in infants younger than 1 month of age. Frequent hematological monitoring is recommended in this instance.

A simplified zidovudine dosing regimen has been developed for use in low resource settings. This regimen consists of 10 mg given twice daily for infants weighing less than 2.5 kg at birth and 15 mg given twice daily for infants weighing more than 2.5 kg at birth. The advantage of this simplified regimen is that it avoids the need for dosing calculations and involves administration of either 1.0 or 1.5 mL of zidovudine syrup. The disadvantage of this dosing regimen is that, compared to mg-per-kg dosing, infants with birth weight greater than 3.75 kg will receive a smaller zidovudine dose and infants less than 3.75 kg will receive a larger zidovudine dose. This regimen could be used for infants in higher resource settings born after 35 weeks gestation if simplicity in zidovudine dosing and administration is of prime importance.

The zidovudine dosing requirements differ for premature infants and term infants. Zidovudine is primarily cleared through hepatic glucuronidation to an inactive metabolite; this metabolic pathway is immature in neonates, leading to prolonged zidovudine half-life and clearance compared to older infants. Because premature infants have even greater immaturity in hepatic metabolic function than full-term infants, further prolongation of clearance is seen *[10-11]*. The recommended zidovudine dosage for infants <35 weeks gestation is 2 mg/kg body weight per dose orally every 12 hours (or 1.5 mg/kg body weight intravenously per dose every 12 hours), increasing to 2 mg/kg body weight per dose every 8 hours at 2 weeks of age if ≥30 weeks gestation at birth or at 4 weeks of age if <30 weeks gestation at birth.

A 4-week neonatal chemoprophylaxis regimen is recommended in the United Kingdom *[12-13]*. This approach may be considered if there are concerns about adherence or toxicity with the 6-week regimen. An observational study in Ireland, where 4 weeks of infant zidovudine post-exposure chemoprophylaxis is standard (given in combination with maternal antiretroviral prophylaxis), reported a transmission rate of 1% in 835 HIV-exposed infants, which may be similar to transmission rates observed in the United States where 6 weeks of infant zidovudine prophylaxis is standard *[13]*. However, the optimal duration of neonatal zidovudine chemoprophylaxis has not been established in clinical trials and in the United States, when there are not concerns about adherence or toxicity, the standard 6-week infant zidovudine regimen is recommended.

General Considerations for Choice of Infant Prophylaxis

In certain situations, some experts combine the 6-week infant zidovudine prophylaxis regimen with additional antiretroviral drugs. Whether combining zidovudine with other antiretroviral drugs provides additional efficacy for prevention of transmission has not been proven in clinical trials. Additionally, appropriate drug formulations and dosing regimens for neonates are incompletely defined and there are minimal data about the safety of combination drugs in the neonate (see **Short-Term Antiretroviral Drug Safety and Choice for Neonatal Prophylaxis** and the ***Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection***). Therefore, the use of combination antiretroviral prophylaxis for the infant involves balancing potential benefits (in terms of preventing perinatal HIV transmission) with risks (in terms of toxicity to the infant).

Infants born to mothers who have received standard antepartum and intrapartum antiretroviral prophylaxis and have undetectable viral load are at very low risk of HIV transmission. However, the risk of transmission is increased when the mother has high viral load at delivery or when the mother has not received the full antepartum and/or intrapartum prophylaxis regimen. In such situations, some experts feel that the potential benefit of combining zidovudine infant prophylaxis with additional antiretroviral drugs may exceed the risk of multiple drug exposure to the infant. These situations include:

a. infants born to mothers who received antepartum and intrapartum antiretroviral drugs but who had suboptimal viral suppression at delivery, particularly if the infant was delivered vaginally;

b. infants born to mothers who received only intrapartum antiretroviral drugs;

c. infants born to mothers who received no antepartum or intrapartum antiretroviral drugs; and

d. infants born to mothers with known antiretroviral drug-resistant virus.

In each of these situations, there is a spectrum of transmission risk that will depend on a number of maternal and infant factors (e.g., maternal viral load, mode of delivery, gestational age at delivery); the risks and benefits of infant exposure to antiretroviral drugs in addition to zidovudine will differ depending on where the mother/child falls in that risk spectrum. For example, an infant born vaginally to a mother with a delivery HIV RNA level of ≥100,000 copies/mL has a higher risk of acquiring HIV infection than an infant born by cesarean delivery to a mother with a delivery HIV RNA level of approximately 10,000 copies/mL. Thus, a generic recommendation regarding use of combination drug regimens in these situations cannot be made and each situation needs to be considered individually. There are no data evaluating the efficacy of specific combination regimens in this situation and the choice of drugs in the neonate is limited (see **Short-Term Antiretroviral Drug Safety and Choice for Neonatal Prophylaxis**). Decisions to use combination infant antiretroviral prophylaxis should be made in consultation with a pediatric HIV specialist before delivery and should be accompanied by a discussion with the mother of the potential risks and benefits of this approach.

Antiretroviral combinations with the greatest experience in neonates are zidovudine in combination with single-dose nevirapine and the dual NRTI combination of zidovudine and lamivudine combined with and/or without the NNRTI nevirapine. Newborn and neonatal dosing information is not available for either nelfinavir or the currently available boosted PIs. Caution should be exercised when using ritonavir or boosted PIs in neonates because both ritonavir and lopinavir/ritonavir have been reported to cause heart block. Careful infant monitoring is needed if combination drugs are provided (see **Long-Term Follow-Up of Antiretroviral Drug-Exposed Infants**).

The National Perinatal HIV Hotline (1-888-448-8765)

The **National Perinatal HIV Hotline** is a federally funded service providing free clinical consultation to providers caring for HIV-infected pregnant women and their infants.

Infant Antiretroviral Prophylaxis Recommendations for Specific Clinical Situations

Infants Born to Mothers Who Received Antepartum/Intrapartum Antiretroviral Drugs with Effective Viral Suppression

Infants born to women who received standard antiretroviral prophylaxis regimens during pregnancy and labor and had undetectable viral load at delivery, or born to mothers with low viral load at delivery and delivered by cesarean section, have a very small risk of HIV acquisition. For example, in PACTG 316, the infection rate in infants born to women receiving antepartum PI-based therapy was 0.7% of 269 infants if delivery HIV RNA was <400 copies/mL *[4]*. Such infants should receive the 6-week zidovudine infant prophylaxis regimen. The benefit of combining zidovudine with additional antiretroviral drugs in reducing transmission in this situation would be very limited and this combination is not recommended.

Infants Born to Mothers Who Have Received Antepartum/Intrapartum Antiretroviral Drugs but Have Suboptimal Viral Suppression near Delivery

The risk of perinatal transmission is related to maternal antepartum viral load in women receiving antiretroviral drugs as well as in antiretroviral-naïve women *[14-16]*. Scheduled cesarean delivery is recommended for prevention of perinatal transmission for women who have received antepartum antiretroviral drugs but have detectable viremia near the time of delivery (i.e., HIV RNA >1,000 copies/mL) (see **Intrapartum Care** and **Transmission and Mode of Delivery**). In PACTG 316, transmission occurred in 0% of 17 infants when maternal delivery HIV RNA was >10,000 copies/mL and the infant was born by scheduled cesarean delivery *[4]*. However, not all women with detectable viremia near delivery will undergo cesarean delivery. Infants born to mothers with higher viral load near delivery, particularly if delivered vaginally, will have a greater risk

of HIV acquisition. There is a gradient of transmission risk based on HIV RNA levels as well as type of maternal antiretroviral therapy. In the Women and Infants Transmission Study, the risk of HIV transmission in women receiving triple combination antiretroviral prophylaxis was ≤1.8% in women with delivery HIV RNA <30,000 copies/mL and increased to 4.8% in women with HIV RNA ≥30,000 copies/mL *[16]*.

There are no data to address whether a more intensive combination infant prophylaxis regimen when the mother has detectable viremia near delivery provides further protection against transmission or at what level of viremia this risk becomes significant enough to outweigh the potential risks of infant combination antiretroviral exposure.

All infants should receive zidovudine for 6 weeks. As discussed earlier (see **Intrapartum Care**), in the PACTG 316 study, the addition of single-dose maternal/infant nevirapine did not reduce the risk of transmission among women who were receiving primarily combination therapy during pregnancy; there were no significant differences in transmission rates between the single-dose nevirapine or placebo groups in any HIV RNA subgroup, although only a small proportion (11%) of the women had HIV RNA levels >10,000 copies/mL at delivery. Given the lack of additional efficacy of single-dose nevirapine in this study and the risk of nevirapine resistance in the mother (and the infant should the infant become infected despite prophylaxis), addition of maternal/infant single-dose nevirapine is not recommended in this situation. Some experts would consider the use of dual or triple antiretroviral drug infant prophylaxis in selected circumstances (e.g., infants born vaginally to mothers with very high viral load near delivery).

Infants Born to Mothers Who Received Only Intrapartum Antiretroviral Drugs

All infants whose mothers have received only intrapartum antiretroviral drugs should be given zidovudine for 6 weeks. The post-exposure prophylaxis provided by the 6-week course of infant zidovudine treatment is a critical component of prevention when no maternal antepartum antiretroviral drugs have been received. The PETRA study demonstrated that intrapartum prophylaxis alone, without an infant post-exposure prophylaxis component, is not effective in reducing perinatal transmission *[5]*. Additionally, a study in Thailand indicated that when the mother has <4 weeks of antenatal zidovudine, longer infant zidovudine prophylaxis (6 weeks compared to 3 days) is required for optimal efficacy *[17]*.

As discussed in the **Intrapartum Care** section, in this situation, some experts would add maternal/infant single-dose nevirapine to the standard intravenous intrapartum/6-week infant zidovudine regimen. This situation differs from that studied in PACTG 316 because, in this circumstance, the mother has received no antepartum antiretroviral drugs. Nevirapine resistance can occur in infants exposed to single-dose nevirapine who become infected despite prophylaxis. The addition of at least 7 days of lamivudine to the 6-week infant zidovudine regimen may reduce the development of nevirapine resistance in such infants, similar to what is recommended for women receiving single-dose nevirapine (see **Intrapartum Care** and **Table 7**) *[18-19]*. However, although all HIV-infected mothers exposed to single-dose nevirapine are at risk of resistance, only a small proportion of infants exposed to single-dose nevirapine become infected and would benefit from the addition of lamivudine. Combination zidovudine/lamivudine may be associated with more severe hematologic toxicity than zidovudine alone (see **Short-Term Antiretroviral Drug Safety and Choice for Neonatal Prophylaxis** and see **Table 8** for dosing information), and more frequent hematologic monitoring of infants receiving this combination is recommended, particularly if it is given for more than 1 week *[20]*.

Although controversial, other experts might consider use of dual or triple antiretroviral drug infant prophylaxis for 6 weeks in this situation because maternal viral load at delivery will not be known and no antenatal therapy has been administered.

Infants Born to Mothers Who Did Not Receive Antepartum or Intrapartum Antiretroviral Drugs

Infants of HIV-infected mothers who have received neither antepartum nor intrapartum antiretroviral drugs should be started on prophylactic zidovudine as soon as possible after delivery. Observational studies suggest that post-exposure prophylaxis to the infant alone may be helpful in preventing HIV transmission. Epidemiologic data from a New York State study indicate a decline in transmission when infants were given zidovudine for the first 6 weeks of life compared to no prophylaxis *[21]*. Transmission rates were 9% (95% CI = 4.1%–17.5%) with zidovudine prophylaxis of newborns only (initiated within 48 hours after birth) versus 27% (95% CI = 21%–33%) with no zidovudine prophylaxis. For most infants in this study, prophylaxis was initiated within 12 hours *[22]*. Thus, when no maternal antepartum or intrapartum antiretroviral drugs have been received, the 6-week infant zidovudine prophylaxis regimen should be initiated as soon as possible after birth.

The interval during which post-exposure prophylaxis can be initiated and still be of benefit is undefined. When prophylaxis was delayed beyond 48 hours after birth in the New York State study, no efficacy could be demonstrated. Data from studies of animals indicate that the longer the delay in institution of prophylaxis, the less likely that infection will be prevented. In most studies of animals, antiretroviral prophylaxis initiated 24 to 36 hours after exposure has usually not been effective for preventing infection, although later administration has been associated with decreased viremia *[23-25]*. Initiation of post-exposure prophylaxis after 2 days of age is not likely to be efficacious in preventing transmission and, by age 14 days, infection would already be established in most infants *[26]*.

Some clinicians view this situation as analogous to nosocomial post-exposure prophylaxis *[27]* and may decide to provide zidovudine in combination with one or more other antiretroviral agents. However, there are no clinical trial data to demonstrate increased efficacy of combination antiretroviral drugs with 6-week zidovudine for infant-only post-exposure prophylaxis in nonbreastfeeding populations, although there is a clinical trial ongoing in the United States, South America, and South Africa.

Data are not available to demonstrate that 6 weeks of infant zidovudine combined with infant single-dose nevirapine at birth is superior to 6 weeks of zidovudine alone. A clinical trial of infant post-exposure prophylaxis in breastfeeding infants in Malawi (see **Lessons from International Clinical Trials of Short-Course Regimens for Prevention of HIV Perinatal Transmission** and **Table 3**) showed that the addition of 1 week of zidovudine to single-dose infant nevirapine was 36% more effective in reducing perinatal transmission compared to single-dose infant nevirapine alone *[7]*. Although this situation is not analogous to adding nevirapine to 6 weeks of zidovudine, particularly in formula-fed infants, some experts would provide single-dose nevirapine at birth to the infant in this situation with the addition of at least 7 days of lamivudine to reduce the risk of nevirapine resistance should the infant become infected (see **Table 8** for dosing information).

Although controversial, other experts might consider use of triple drug combination therapy in the infant for the 6-week prophylaxis period, similar to occupational post-exposure prophylaxis.

Infants Born to Mothers with Antiretroviral Drug-Resistant Virus

The optimal prophylactic regimen for newborns of women with antiretroviral drug-resistant virus is unknown. Antiretroviral prophylaxis for an infant born to a woman with known or suspected drug resistance should be determined in consultation with a pediatric HIV specialist before delivery.

Data from the Women and Infants Transmission Study (WITS) suggest that in women who have mixed zidovudine-resistant and zidovudine-sensitive viral populations, the zidovudine-sensitive rather than -resistant virus may be preferentially transmitted *[28-29]* (see **Table 7**). Thus, the 6-week infant zidovudine prophylaxis (along with maternal intravenous intrapartum zidovudine prophylaxis) continues to be recommended even when maternal zidovudine-resistant virus with thymidine-associated mutations (TAMs) is identified.

There have been some studies suggesting that antiretroviral drug-resistant virus may have decreased replicative capacity (reduced viral fitness) and transmissibility *[29]*. However, transmission of multi-drug resistant virus from mother to child has been reported *[30-32]*.

The use of zidovudine in combination with other antiretroviral drugs selected on the basis of maternal virus resistance testing may be considered for these newborns. The efficacy of this approach for prevention of transmission has not been proven in clinical trials, and appropriate dosing regimens for neonates are incompletely defined for many drugs. Decisions regarding use of additional drugs will depend on the history of maternal past and current antiretroviral drug exposure, HIV RNA level at or near delivery, current and previous maternal resistance testing, and availability of drug formulation and dosing information in the infant. Additional antiretroviral drugs that can be added to zidovudine include lamivudine and nevirapine.

Short-Term Antiretroviral Drug Safety and Choice for Neonatal Prophylaxis

Short-term toxicity of infant zidovudine prophylaxis has been minimal, consisting primarily of transient hematologic toxicity, mainly anemia, which generally resolves by age 12 weeks. Data on the toxicity of multiple antiretroviral drug exposure for the infant are limited.

The latest information on neonatal dosing for antiretroviral drugs can be found in the ***Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection***. Other than zidovudine, the NRTI with the most experience in use for neonatal prophylaxis is lamivudine, although neonatal exposure to combination zidovudine/lamivudine has generally been limited to 1 week *[5-6, 33]*. Six weeks of infant zidovudine/lamivudine exposure has been reported in a few studies; these studies suggest that hematologic toxicity may be increased over that seen with zidovudine alone, although the infants also had *in utero* exposure to maternal combination therapy. In a French study where 6 weeks of zidovudine/lamivudine was provided for infant prophylaxis in infants who were also exposed to antepartum zidovudine/lamivudine, more severe anemia and neutropenia were observed than in a historical cohort exposed only to zidovudine; anemia was observed in 15% and neutropenia in 18% of infants exposed to zidovudine/lamivudine, with 2% of infants requiring blood transfusion and 4% requiring treatment discontinuation for toxicity *[34]*. Similarly, in a Brazilian study using maternal antepartum and 6-week infant zidovudine/lamivudine prophylaxis, neonatal hematologic toxicity was common, with anemia seen in 69% and neutropenia in 13% of infants *[35]*. In a Phase I study of stavudine in pregnant women, infants received 6 weeks of zidovudine/lamivudine and a single dose of stavudine at age 1 and 6 weeks; 43% of 14 infants experienced grade 3 hematologic toxicity after birth (36% neutropenia and 7% anemia) *[36]*. Finally, in 3 Phase I studies of PIs (saquinavir/ritonavir, indinavir, or nelfinavir) in pregnancy, a total of 52 infants received 6 weeks of zidovudine/lamivudine (in 26 infants, zidovudine/lamivudine was combined with nelfinavir); grade 2 or higher hematologic toxicity was observed in 46% to 62% of infants *[37-39]*. Experience with other NRTI drugs for neonatal prophylaxis is more limited *[40-41]*. Hematologic and mitochondrial toxicity may be more common with exposure to multiple versus single NRTI drugs *[34, 42-45]*.

Nevirapine is the only NNRTI drug with a pediatric drug formulation and neonatal dosing information (see ***Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection***). Chronic, multiple-dose nevirapine can be rarely associated with severe and potentially life-threatening rash and hepatic toxicity. These toxicities have not been observed in infants receiving single-dose nevirapine or in breastfeeding infants receiving 6 to 14 weeks of daily infant nevirapine prophylaxis to prevent transmission of HIV via breast milk *[46-47]*. However, nevirapine drug resistance may occur with exposure to single-dose nevirapine should the infant become infected despite prophylaxis (see **Table 7**). If multiple-dose daily nevirapine is used as part of a combination infant prophylaxis regimen, some experts would stop nevirapine first and continue the other drugs for a period of time (e.g., at least 7 days). This drug administration strategy is adopted because the prolonged half-life of nevirapine in infants results in a period of persistent subtherapeutic level of nevirapine if all drugs are stopped simultaneously, resulting in a risk of nevirapine resistance should the infant become infected

despite prophylaxis. Antiretroviral drug resistance testing is recommended prior to initiation of antiretroviral therapy in all HIV-infected infants (see ***Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection***).

Of the PIs, nelfinavir, lopinavir/ritonavir, ritonavir, tipranavir, and fosamprenavir have pediatric drug formulations. However, dosing information for newborn infants is available only for nelfinavir, which has highly variable levels in neonates and requires high doses (more than 45 mg/kg body weight twice daily and possibly as high as 75 mg/kg body weight twice daily) to achieve target levels (see ***Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection***) *[39, 41]*. Pharmacokinetic data for treatment of HIV-infected infants aged 2 to 6 weeks of age with lopinavir/ritonavir are available. Although the lopinavir area under the curve with dosing 300 mg lopinavir/75 mg ritonavir per meter^2 body surface area twice daily was significantly lower than observed for infants older than 6 weeks, treatment was well tolerated, and 80% of 10 infants had viral control at 6 months *[48]*. Although under study, data are not yet available for infants younger than 2 weeks of age. However, there have been 4 premature infants (2 sets of twins) started on lopinavir/ritonavir from birth who developed heart block that resolved following discontinuation of the drug *[49-50]*. In studies of adults, both ritonavir and lopinavir/ritonavir cause dose-dependent prolongation of the PR interval and cases of significant heart block, including complete heart block, have been reported.

Dosing for premature infants is only available for zidovudine (see **Table 7**), making use of additional antiretroviral drugs more problematic in this group. Renal and hepatic metabolism is immature in preterm infants, which increases the risk of overdosing and toxicity. Additionally, zidovudine is the only antiretroviral drug available in intravenous formulation. Therefore, the 6-week zidovudine prophylaxis regimen is recommended for preterm infants at gestational age-appropriate doses. Use of antiretroviral drugs other than zidovudine cannot be recommended in premature infants due to lack of dosing and safety data.

Initial Postnatal Management of the HIV-Exposed Neonate

Panel's Recommendations:

- ***A complete blood count (CBC) and differential should be performed on the newborn as a baseline evaluation (BIII).***
- ***Decisions about the timing of subsequent monitoring of the hematologic parameters in the infant will depend on baseline hematologic values, gestational age at birth, clinical condition of the infant, dose of zidovudine being administered, receipt of concomitant medications, and maternal antepartum therapy (CIII).***
- ***Some experts recommend more intensive monitoring of hematologic and serum chemistry and liver function assays during the first few weeks of life for infants exposed to combination antiretroviral therapy in utero or during the neonatal period (CIII).***
- ***If hematologic abnormalities are identified while the infant is receiving prophylaxis, decisions on whether to continue infant antiretroviral prophylaxis need to be individualized. Consultation with an expert in pediatric HIV infection is advised if discontinuation of prophylaxis is considered (CIII).***
- ***Routine measurement of serum lactate is not recommended. However, measurement of serum lactate may be considered if an infant develops severe clinical symptoms of unknown etiology (particularly neurologic symptoms) (CIII).***
- ***Virologic tests are required to diagnose HIV infection in infants <18 months of age and should be performed at a minimum at ages 14 to 21 days, 1 to 2 months, and 4 to 6 months (AII).***
- ***To prevent Pneumocystis jirovecci pneumonia (PCP), all infants born to women with HIV infection should begin PCP prophylaxis at age 4–6 weeks, after completion of the zidovudine prophylaxis regimen, unless there is adequate test information to presumptively exclude HIV infection (see USPHS/IDSA Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Exposed and Infected Children) (AIII).***

A CBC and differential should be performed on the newborn as a baseline evaluation before administration of zidovudine. Anemia has been the primary complication of the 6-week zidovudine regimen in the neonate. In PACTG 076, infants in the zidovudine group had lower hemoglobin at birth than infants in the placebo group, with the maximal difference (1 gm/dL) occurring at age 3 weeks *[3]*. The lowest mean value for hemoglobin (10 gm/dL) occurred at 6 weeks of age in the zidovudine group. By 12 weeks of age, hemoglobin values in both groups were similar. No significant differences in other laboratory parameters were observed between groups.

Decisions about the timing of subsequent hematologic monitoring of infants following birth will depend on a number of factors, including baseline hematologic values, gestational age at birth, clinical condition of the infant, dose of zidovudine being administered, receipt of concomitant medications, and maternal antepartum therapy. Some experts re-check hematologic values in healthy infants receiving zidovudine prophylaxis only if the child is symptomatic, although others re-check hemoglobin and neutrophil count after 4 weeks of zidovudine prophylaxis.

If hematologic abnormalities are found, decisions on whether to continue infant antiretroviral prophylaxis need to be individualized. Considerations include the extent of the abnormality, whether the infant has related symptoms, duration of infant prophylaxis received, the risk of HIV infection in the infant (as assessed by whether the mother had received antiretroviral prophylaxis, her viral load near delivery, and mode of delivery), and availability of alternative interventions (e.g., erythropoietin, transfusion). Consideration may be given to reducing the duration of infant prophylaxis from 6 to 4 weeks. Consultation with an expert in pediatric HIV infection is advised if discontinuation of prophylaxis is considered.

Data are limited concerning potential toxicities in infants whose mothers have received combination antiretroviral therapy or when the infant receives more than zidovudine prophylaxis. Some studies suggest a higher incidence of anemia and/or neutropenia in infants who receive zidovudine prophylaxis but are born to mothers who received combination therapy compared to infants born to mothers who received only zidovudine during pregnancy *[45, 51-52]*. In PACTG 316, where 77% of mothers received antenatal combination therapy, significant grade 3 or higher anemia was seen in 13% and neutropenia in 12% of infants. Additionally, as discussed earlier, higher rates of hematologic toxicity have been observed in infants receiving zidovudine/lamivudine combination prophylaxis than in those receiving zidovudine alone.

Thus, more intensive monitoring of hematologic values and serum chemistry and liver function assays during the first few weeks of life is advised for these infants, based on what is known about the side effects of the drugs. For example, because hepatic toxicity is observed with most of the antiretroviral drugs, measurement of baseline liver transaminase levels in infants with exposure to multiple antiretroviral drugs *in utero* or receiving infant combination drug prophylaxis might be considered. Hematologic toxicity appears to be more significant in infants who receive both zidovudine and lamivudine as infant prophylaxis for 6 weeks and who were exposed to antepartum zidovudine/lamivudine. More frequent monitoring of hematologic values in these infants versus in infants who receive only zidovudine prophylaxis might be considered *[34]*. Additionally, as previously stated, hematologic safety data with administration of double the standard dose of zidovudine twice daily in infants under a month of age are inadequate. More frequent hematological monitoring is also recommended in this instance.

Although hyperlactatemia has been reported in infants with *in utero* antiretroviral exposure, this appears transient and in most cases asymptomatic *[53-54]*. Routine measurement of serum lactate in asymptomatic neonates to assess for potential mitochondrial toxicity is not recommended because the clinical relevance is unknown and predictive value for toxicity appears poor *[53-54]*. However, should an infant develop severe clinical symptoms of unknown etiology, particularly neurologic symptoms, obtaining serum lactate should be considered. If serum lactate is significantly abnormal (>5 mmol/L) in an infant with symptoms, antiretroviral prophylaxis should be discontinued and an expert in pediatric HIV infection should be consulted regarding potential alternate prophylaxis.

To prevent *Pneumocystis jirovecii* pneumonia (PCP), all infants born to women with HIV infection should begin trimethoprim-sulfamethoxazole prophylaxis at age 6 weeks, after completion of the zidovudine prophylaxis, unless there is adequate virologic test information to presumptively exclude HIV infection (see ***USPHS/IDSA Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Exposed and Infected Children***) *[2]*.

HIV infection in infants should be diagnosed using HIV DNA PCR or RNA virologic assays. Maternal HIV antibody crosses the placenta and will be detectable in all HIV-exposed infants up to 18 months of age; therefore, standard antibody tests should not be used for HIV diagnosis in newborns. HIV virologic testing should be performed at a minimum at ages 14 to 21 days, 1 to 2 months, and 4 to 6 months *[55]*. Some experts also perform a virologic test at birth, especially if the woman has not had good virologic control during pregnancy or if adequate follow-up of the infant may not be assured. A positive HIV virologic test should be confirmed as soon as possible with a second HIV virologic test on a different specimen. Two positive HIV tests constitute a diagnosis of HIV infection. Data do not indicate any delay in HIV diagnosis with HIV DNA PCR assays in infants who have received the zidovudine regimen *[3, 56]*. However, the effect of combination antiretroviral therapy in the mother or newborn on the sensitivity of infant virologic diagnostic testing, particularly using HIV RNA assays, is unknown. Therefore, although HIV RNA assays may be acceptable for diagnosis (particularly in older infants), HIV DNA PCR assays may be more optimal for diagnosing infection in the neonatal period.

HIV may be presumptively excluded with two or more negative tests with one at ≥14 days and another at ≥1 month of age. Definitive exclusion of HIV in nonbreastfed infants may be based on two negative virologic

tests at ≥1 month and ≥4 months of age. Many experts confirm HIV-negative status with an HIV antibody test at age 12 to 18 months. (Alternative algorithms exist for presumptive and definitive HIV exclusion *[55]*.)

Following birth, HIV-exposed infants should have a detailed physical examination and a thorough maternal history should be obtained. The HIV-infected mother may be coinfected with other pathogens that can be transmitted from mother to child, such as cytomegalovirus, herpes simplex virus, hepatitis B, hepatitis C, syphilis, toxoplasmosis, or tuberculosis. Infants born to mothers with such coinfections should undergo appropriate evaluation as indicated by maternal CD4 count and evidence of disease activity to rule out transmission of additional infectious agents. HIV-exposed infants born to HIV-infected mothers should follow the routine primary immunization schedule. Infants with known HIV infection may require modifications in the schedule for live virus vaccines (see ***USPHS/IDSA Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Exposed and Infected Children***).

Infant Feeding Practices and the Risk of HIV Transmission

In the United States, where safe infant feeding alternatives are available and free for women in need, HIV-infected women should not breastfeed their infants. Postnatally, mothers should be advised that although antiretroviral therapy is likely to reduce free virus in the plasma, the presence of cell-associated virus (intracellular HIV DNA) remains unaffected and may therefore continue to pose a transmission risk *[57]*.

Late HIV transmission events in infancy have recently been reported from three HIV-infected children. In each case HIV infection is suspected to have occurred as a result of infant consumption of premasticated food given to them from their caregivers. Phylogenetic comparisons of virus from cases and suspected sources and supporting clinical history and investigations identified the practice of feeding premasticated foods to infants as a potential risk factor for HIV transmission. Health care providers should routinely inquire about this feeding practice and instruct HIV-infected caregivers on safer feeding options *[58]*.

Long-Term Follow-Up of Antiretroviral Drug-Exposed Infants

Panel's Recommendations:

- ***Children with in utero/neonatal antiretroviral exposure who develop significant organ system abnormalities of unknown etiology, particularly of the nervous system or heart, should be evaluated for potential mitochondrial dysfunction (CIII).***
- ***Follow-up of children with antiretroviral exposure should continue into adulthood because of the theoretical concerns regarding the potential for carcinogenicity of the nucleoside analogue antiretroviral drugs (CIII).***

Data remain insufficient to address the effect that exposure to zidovudine or other antiretroviral agents *in utero* might have on long-term risk of neoplasia or organ system toxicities in children. Data from follow-up of PACTG 076 infants through age 6 years do not indicate any differences in immunologic, neurologic, and growth parameters between infants who were exposed to the zidovudine regimen and those who received placebo, and no malignancies have been seen *[59-61]*. As discussed earlier in the section on **NRTI Drugs and Mitochondrial Toxicity**, there are conflicting data regarding whether mitochondrial dysfunction is associated with perinatal antiretroviral exposure. Mitochondrial dysfunction should be considered in uninfected children with perinatal antiretroviral exposure who present with severe clinical findings of unknown etiology, particularly neurologic findings.

Continued evaluation of early and late effects of *in utero* antiretroviral exposure is ongoing through several mechanisms, including the Pediatric HIV/AIDS Cohort Study (PHACS), Surveillance Monitoring of Antiretroviral Toxicity Study, natural history studies, and HIV/AIDS surveillance conducted by state health departments and CDC. Because most of the available follow-up data relate to *in utero* exposure to antenatal

zidovudine alone and most pregnant women with HIV infection currently receive combination therapy, it is critical that studies to evaluate potential adverse effects of *in utero* drug exposure continue to be supported.

Innovative methods are needed to provide follow-up of infants with *in utero* exposure to antiretroviral drugs. Information regarding such exposure should be part of the ongoing permanent medical record of the child, particularly for uninfected children. Children with *in utero* antiretroviral exposure who develop significant organ system abnormalities of unknown etiology, particularly of the nervous system or heart, should be evaluated for potential mitochondrial dysfunction *[62-64]*. Follow-up of children with antiretroviral exposure should continue into adulthood because of the theoretical concerns regarding the potential for carcinogenicity of the nucleoside analogue antiretroviral drugs. Long-term follow-up should include yearly physical examinations of all children exposed to antiretroviral drugs.

HIV surveillance databases from states that require HIV reporting provide an opportunity to collect population-based information concerning *in utero* antiretroviral exposure. To the extent permitted by federal law and regulations, data from these confidential registries can be used to compare with information from birth defect and cancer registries to identify potential adverse outcomes.

Supplement: Safety and Toxicity of Individual Antiretroviral Agents in Pregnancy

(Updated May 24, 2010)

Glossary of Terms for Supplement

Clastogenic: causing disruption or breakages of chromosomes

Mutagenic: inducing or capable of inducing genetic mutation

Genotoxic: damaging to genetic material (e.g., DNA, chromosomes)

Carcinogenic: producing or tending to produce cancer

Notes: (1) Some agents (e.g., certain chemicals or forms of radiation) are both mutagenic and clastogenic. (2) Genetic mutations and/or chromosome damage can contribute to cancer formation.

NUCLEOSIDE AND NUCLEOTIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS

Six nucleoside analogue reverse transcriptase inhibitors are currently approved (zalcitabine is no longer available in the United States). Data are available from clinical trials in human pregnancy for zidovudine, abacavir, lamivudine, didanosine, emtricitabine, and stavudine. Tenofovir disoproxil fumarate is the first nucleotide analogue reverse transcriptase inhibitor. The nucleoside analogue drugs require three intracellular phosphorylation steps to form the triphosphate nucleoside, which is the active drug moiety. Tenofovir, an acyclic nucleotide analogue drug, contains a monophosphate component attached to the adenine base, and hence only requires two phosphorylation steps to form the active moiety.

For information regarding the nucleoside analogue drug class and potential mitochondrial toxicity in pregnancy and to the infant, see **NRTI Drugs and Mitochondrial Toxicity** in the Perinatal Guidelines.

Abacavir (Ziagen, ABC) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Abacavir is mutagenic and clastogenic in some *in vitro* and *in vivo* assays. In long-term carcinogenicity studies in mice and rats, malignant tumors of the preputial gland of males and the clitoral gland of females were observed in both species, and malignant hepatic tumors and nonmalignant hepatic and thyroid tumors were observed in female rats. The tumors were seen in rodents at doses that were 6 to 32 times that of human therapeutic exposure.
- Reproduction/fertility
  No effect of abacavir on reproduction or fertility in male and female rodents has been seen at doses of up to 500 mg/kg/day (about 8 times that of human therapeutic exposure based on body surface area).
- Teratogenicity/developmental toxicity
  Abacavir is associated with developmental toxicity (decreased fetal body weight and reduced crown-rump length) and increased incidence of fetal anasarca and skeletal malformations in rats treated with abacavir

during organogenesis at doses of 1,000 mg/kg (about 35 times that of human therapeutic exposure based on area under the curve [AUC]). Toxicity to the developing embryo and fetus (increased resorptions and decreased fetal body weight) occurred with abacavir administration of 500 mg/kg/day to pregnant rodents. The offspring of female rats treated with 500 mg/kg of abacavir beginning at embryo implantation and ending at weaning had an increased incidence of stillbirth and lower body weight throughout life. However, in the rabbit, no evidence of drug-related developmental toxicity was observed and no increase in fetal malformations was observed at doses up to 700 mg/kg (about 8.5 times that of human therapeutic exposure).

In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to abacavir in humans have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with abacavir. The prevalence of birth defects with first-trimester abacavir exposure was 3.0% (19/628, 95% CI: 1.8%–4.7%) comparedto total prevalence of birth defects in the U.S. population based on Centers for Disease Control and Prevention (CDC) surveillance of 2.7% *[1]*.

- Placental and breast milk passage
  Abacavir crosses the placenta and is excreted into the breast milk of lactating rats.
- Human studies in pregnancy
  A Phase I study of abacavir in pregnant women indicates that the AUC drug concentration during pregnancy was similar to that at 6 to 12 weeks postpartum and to nonpregnant individuals *[2]*. Thus, no dose adjustment for abacavir is needed during pregnancy. Serious hypersensitivity reactions have been associated with abacavir therapy in nonpregnant adults and have rarely been fatal; symptoms include fever, skin rash, fatigue, and gastrointestinal symptoms such as nausea, vomiting, diarrhea, or abdominal pain. Abacavir should not be restarted following a hypersensitivity reaction because more severe symptoms will recur within hours and may include life-threatening hypotension and death.

2. Best BM, Mirochnick M, Capparelli EV, et al. Impact of pregnancy on abacavir pharmacokinetics. *AIDS*, 2006. 20(4):553-60. http://www.ncbi.nlm.nih.gov/pubmed/16470119

Didanosine (Videx, ddI) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Didanosine is both mutagenic and clastogenic in several *in vitro* and *in vivo* assays. Long-term animal carcinogenicity screening studies at human exposures of 0.7 to 1.7- and 3- times in mice and rats, respectively, have been negative.
- Reproduction/fertility
  At approximately 12 times the estimated human exposure, didanosine was slightly toxic to female rats and their pups during mid- and late- lactation. These rats showed reduced food intake and body weight gains; however, the physical and functional development of the offspring was not impaired and there were no major changes in the F2 generation.
- Teratogenicity/developmental toxicity
  No evidence of teratogenicity or toxicity was observed with administration of didanosine at 12- and 14-times human exposure in pregnant rats and rabbits, respectively. Among cases of first-trimester didanosine exposure reported to the Antiretroviral Pregnancy Registry, defects have been noted in 4.6% (17/370, 95% CI: 2.7%–7.3%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*. All defects were reviewed in detail by the Registry, and no pattern of defects was discovered. The rate and types of defects will continue to be monitored closely.

- Placental and breast milk passage
  Placental transfer of didanosine was limited in a Phase I/II safety and pharmacokinetic study *[2]*. This was confirmed in a study of 100 HIV-infected pregnant women who were receiving NRTIs (generally as part of a two- or three- drug combination antiretroviral regimen). At the time of delivery, cord-to-maternal blood ratio for didanosine (n=10) was 0.38 (range 0.0–2.00) and in 15/24 samples (62%), cord blood concentrations for didanosine were below the limits of detection *[3]*. A study in rats showed that didanosine and/or its metabolites are transferred to the fetus through the placenta. It is not known if didanosine is excreted in human breast milk.

- Human studies in pregnancy
  A Phase I study (PACTG 249) of didanosine was conducted in 14 HIV-infected pregnant women enrolled at gestational age 26 to 36 weeks and treated through 6 weeks postpartum *[2]*. The drug was well tolerated during pregnancy by the women and the fetuses. Pharmacokinetic parameters after oral administration were not significantly affected by pregnancy, and dose modification from the usual adult dosage is not needed.

  Cases of lactic acidosis, in some cases fatal, have been described in pregnant women receiving the combination of didanosine and stavudine along with other antiretroviral agents *[4-6]*; the FDA and Bristol-Myers Squibb have issued a warning to health care professionals that pregnant women may be at increased risk of fatal lactic acidosis when prescribed the combination of didanosine and stavudine (see **NRTI Drugs and Mitochondrial Toxicity** in Perinatal Guidelines). The combination of these two drugs should be prescribed for pregnant women only when the potential benefit clearly outweighs the potential risk. Clinicians should prescribe this antiretroviral combination during pregnancy with caution and generally only when other nucleoside analog drug combinations have failed or have caused unacceptable toxicity or side effects.

Emtricitabine (Emtriva, FTC) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Emtricitabine was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. In long-term oral carcinogenicity studies of emtricitabine, no drug-related increases in tumor incidence were found in mice at doses up to 26 times the human systemic exposure at the therapeutic dose of 200 mg/day or in rats at doses up to 31 times the human systemic exposure at the therapeutic dose.

- Reproduction/fertility
  No effect of emtricitabine on reproduction or fertility was observed with doses that produced systemic drug exposures (as measured by AUC approximately 60-fold higher in female mice and 140-fold higher in male mice than observed with human exposure at the recommended therapeutic dose.

- Teratogenicity/developmental toxicity
  The incidence of fetal variations and malformations was not increased with emtricitabine dosing in mice resulting in systemic drug exposure 60-fold higher than observed with human exposure at recommended doses, or in rabbits with dosing resulting in drug exposure 120-fold higher than human exposure.

  In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to emtricitabine in humans have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with emtricitabine. The prevalence of birth defects with first-trimester emtricitabine exposure was 2.9% (11/384, 95% CI: 1.4%–5.1%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*.

- Placental and breast milk passage
  Emtricitabine has been shown to cross the placenta in mice and rabbits; the average fetal/maternal drug concentration was 0.4 in mice and 0.5 in rabbits *[2]*. Emtricitabine has been shown to have good placental transfer in pregnant women. In 18 women who received 200 mg emtricitabine daily during pregnancy, mean cord blood concentration was 300 ± 268 ng/mL and mean ratios of cord blood/maternal emtricitabine concentrations were 1.17 ± 0.6 (n=9) *[3]*. When 35 women were administered 400 mg of emtricitabine in combination with tenofovir at delivery, median maternal and cord concentrations were 1.02 (0.034–2.04) and 0.74 (0.0005–1.46) mg/L, respectively *[4]*. It is unknown if emtricitabine is excreted in human milk.

- Human studies in pregnancy
  Emtricitabine pharmacokinetics have been evaluated in 18 HIV-infected pregnant women receiving combination antiretroviral therapy including emtricitabine (200 mg once daily) at 30 to 36 weeks gestation and 6 to 12 weeks postpartum *[3]*. Emtricitabine exposure was modestly lower during the third trimester (8.6 µg*h/mL [5.2–15.9]) compared to the postpartum period (9.8 µg*h/mL [7.4–30.3]). Two-thirds (12/18) of pregnant women versus 100% (14/14) of postpartum women met the AUC target (10^{th} percentile in nonpregnant adults). Trough emtricitabine levels were also lower during pregnancy (C_{min} 52 ng/mL [14 – 180]) compared to the postpartum period (86 ng/mL [<10 – 306]). In another study of 35 women who received 400 mg of emtricitabine with tenofovir at delivery, median population AUC, C_{max}, and C_{min} were 14.3 µg*h/mL; 1,680 ng/mL; and 76 ng/mL, respectively *[4]*.

Abstract 629. http://www.retroconference.org/2008/PDFs/629.pdf

Lamivudine (Epivir, 3TC) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Lamivudine has weak mutagenic activity in 1 *in vitro* assay but no evidence of *in vivo* genotoxicity in rats at 35–45 times human exposure. Long-term animal carcinogenicity screening studies at 10- and 58- times human exposure have been negative in mice and rats, respectively.

- Reproduction/fertility
  Lamivudine administered to rats at doses up to 4,000 mg/kg/day, producing plasma levels 47- to 70- times those in humans, revealed no evidence of impaired fertility and no effect on the survival, growth, and development to weaning of the offspring.

- Teratogenicity/developmental toxicity studies
  There is no evidence of lamivudine-induced teratogenicity at 35 times human plasma levels in rats and rabbits. Early embryolethality was seen in rabbits at doses similar to human therapeutic exposure but not in rats at 35 times the human exposure level.

  In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to lamivudine in humans have been monitored to detect at least a 1.5-fold increase in risk of overall birth defects and a 2-fold increase in the most commonly occurring birth defects (e.g., defects of the cardiovascular and genitourinary systems). No such increase in birth defects has been observed with lamivudine. The prevalence of birth defects with first-trimester lamivudine exposure was 2.9% (96/3,314, 95% CI: 2.3%–3.5%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*.

- Placental and breast milk passage
  Lamivudine readily crosses the placenta in humans, achieving comparable cord blood and maternal concentrations*[2]*. Lamivudine is excreted into human breast milk. In a study in Kenya of 67 HIV-infected nursing mothers receiving a combination regimen of zidovudine, lamivudine, and nevirapine, the median breast milk lamivudine concentration was 1,214 ng/mL and the median ratio of lamivudine concentration in breast milk to that in plasma was 2.56 *[3]*. Their infants, who only received lamivudine via breast milk, had a median plasma lamivudine concentration of 23 ng/mL (IC_{50} of wild-type HIV against lamivudine = 0.6 – 21 ng/mL).

- Human studies in pregnancy
  A small Phase I study in South Africa evaluated the safety and pharmacokinetics of lamivudine alone or in combination with zidovudine in 20 HIV-infected pregnant women; therapy was started at 38 weeks gestation, continued through labor, and given for 1 week following birth to the infants*[2]*. The drug was well tolerated in the women at the recommended adult dose of 150 mg orally twice daily; pharmacokinetics were similar to those observed in nonpregnant adults, and no pharmacokinetic interaction with zidovudine was observed.

  Zidovudine and lamivudine, given in combination orally intrapartum, were well-tolerated. Lamivudine was well tolerated in the neonates, but clearance was about 50% that of older children, requiring a reduced dosing regimen (4 mg/kg/day in neonates compared to 8 mg/kg/day for infants older than 3 months). There are currently no data on the pharmacokinetics of lamivudine between 2 and 6 weeks of age, and the exact age at which lamivudine clearance begins to approximate that in older children is not known.

Pharmacokinetics and antiretroviral activity of lamivudine alone or when coadministered with zidovudine in human immunodeficiency virus type 1-infected pregnant women and their offspring. *J Infect Dis*, 1998. 178(5):1327-33. http://www.ncbi.nlm.nih.gov/pubmed/9780252
3. Mirochnick M, Thomas T, Capparelli E, et al. Antiretroviral concentrations in breast-feeding infants of mothers receiving highly active antiretroviral therapy. *Antimicrob Agents Chemother*, 2009. 53(3):1170-6. http://www.ncbi.nlm.nih.gov/pubmed/19114673

Stavudine (Zerit, d4T) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Stavudine is clastogenic in *in vivo* and *in vivo* assays but not mutagenic in *in vitro* assays. In 2-year carcinogenicity studies in mice and rats, stavudine was noncarcinogenic in doses producing exposures 39 (mice) and 168 (rats) times human exposure at the recommended therapeutic dose. At higher levels of exposure (250 [mice] and 732 [rats] times human exposure at therapeutic doses), benign and malignant liver tumors occurred in mice and rats and urinary bladder tumors occurred in male rats.

- Reproduction/fertility
  No effect of stavudine on reproduction or fertility in rodents has been seen. A dose-related cytotoxic effect has been observed on preimplantation mouse embryos, with inhibition of blastocyst formation at a concentration of stavudine of 100 µM and of postblastocyst development at 10 µM *[1]*.

- Teratogenicity/developmental toxicity studies
  No evidence of teratogenicity was noted in rats or rabbits with exposures (based on C_{max}) up to 399 and 183 times, respectively, of that seen at a clinical dosage of 1 mg/kg/day. The incidence in fetuses of a common skeletal variation, unossified or incomplete ossification of sternebra, was increased in rats at 399 times human exposure, although no effect was observed at 216 times human exposure. A slight post-implantation loss was noted at 216 times the human exposure with no effect noted at approximately 135 times the human exposure. An increase in early rat neonatal mortality (birth to 4 days of age) occurred at 399 times the human exposure, although survival of neonates was unaffected at approximately 135 times the human exposure. A study in rats showed that stavudine is transferred to the fetus through the placenta. The concentration in fetal tissue was approximately one-half the concentration in maternal plasma.

  In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to stavudine in humans have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with stavudine. The prevalence of birth defects with first-trimester stavudine exposure was 2.5% (19/771, 95% CI: 1.5%–3.8%) compared with total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[2]*.

- Placental and breast milk passage
  Stavudine crosses the rat placenta *in vivo* and the human placenta *ex vivo*, resulting in a fetal/maternal concentration of approximately 0.50. In primates (pigtailed macaques), fetal/maternal plasma concentrations were approximately 0.80 *[3]*. Stavudine is excreted into the breast milk of lactating rats.

- Human studies in pregnancy
  A Phase I/II safety and pharmacokinetic study of combination stavudine and lamivudine in pregnant HIV-infected women and their infants has been conducted (PACTG 332). Both drugs were well tolerated, with pharmacokinetics similar to those in nonpregnant adults *[4]*. Data from primate studies also indicated that pregnancy did not affect the pharmacokinetics of stavudine *[5]*.

  Cases of lactic acidosis, in some cases fatal, have been described in pregnant women receiving the combination of didanosine and stavudine along with other antiretroviral agents *[6-8]*. The FDA and Bristol-Myers Squibb have issued a warning to health care professionals that pregnant women may be at increased risk of fatal lactic acidosis when prescribed the combination of didanosine and stavudine (see **NRTI Drugs and Mitochondrial Toxicity** in the Perinatal Guidelines). The combination of these two drugs should be prescribed for pregnant women only when the potential benefit clearly outweighs the potential risk. Clinicians should prescribe this antiretroviral combination during pregnancy with caution and generally only when other nucleoside analog drug combinations have failed or have caused unacceptable toxicity or side effects.

Tenofovir disoproxil fumarate (Viread, TDF) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Tenofovir is mutagenic in one of two *in vitro* assays and has no evidence of clastogenic activity. Long-term oral carcinogenicity studies of tenofovir DF in mice and rats were carried out at 16 times (mice) and 5 times (rats) human exposure. In female mice, liver adenomas were increased at exposures 16 times that observed in humans at therapeutic doses. In rats, the study was negative for carcinogenic findings at exposures up to 5 times that observed in humans at the therapeutic dose.

- Reproduction/fertility
  Reproduction studies have been performed in rats and rabbits at doses up to 14 and 19 times the human dose based on body surface area comparisons and revealed no evidence of impaired fertility or harm to the fetus due to tenofovir. There were also no effects on fertility, mating performance, or early embryonic development when tenofovir disoproxil fumarate was administered to male rats (600 mg/kg/day; equivalent to 10 times the human dose based on body surface area) for 28 days prior to mating and to female rats for 15 days prior to mating through Day 7 of gestation. There was, however, an alteration of the estrous cycle in female rats administered 600 mg/kg/day.

- Teratogenicity/developmental toxicity
  Chronic exposure of fetal monkeys to tenofovir at a high dose of 30 mg/kg (exposure equivalent to 25 times the AUC achieved with therapeutic dosing in humans) from Days 20–150 of gestation did not result in gross structural abnormalities *[1]*. However, significantly lower fetal circulating insulin-like growth factor (IGF)-1 (a primary regulator of linear growth) and higher IGF binding protein (IGFBP)-3 levels were shown and were associated with overall body weights approximately 13% lower than untreated controls. A slight reduction in fetal bone porosity was also observed. Effects on these parameters were observed within 2 months of maternal treatment. Significant changes in maternal monkey bone biomarkers were noted but were primarily limited to the treatment period and were reversible.

  Continued administration of tenofovir at 30 mg/kg/day to the infant monkey postnatally resulted in significant growth restriction and severe bone toxicity in 25% of 8 infants and effects on bone biomarkers and defective bone mineralization in all animals. Chronic administration of tenofovir to immature animals of multiple species has resulted in reversible bone abnormalities; these effects were dose-, exposure-, age-, and species specific. Abnormalities ranged from minimal decrease in bone mineral density and content (with oral dosing in rats and dogs that achieved drug exposures 6 to 10 times that achieved with therapeutic dosing in

humans) to severe, pathologic osteomalacia (with subcutaneous dosing given to monkeys). Juvenile monkeys given chronic subcutaneous tenofovir at 30 mg/kg/day (exposure equivalent to 25 times the AUC achieved with therapeutic dosing in humans) developed osteomalacia, bone fractures, and marked hypophosphatemia. However, no clinical or radiologic bone toxicity was seen when juvenile monkeys received subcutaneous dosing of 10 mg/kg/day (exposure equivalent to 8 times the AUC achieved with therapeutic dosing in humans). Evidence of nephrotoxicity was observed in newborn and juvenile monkeys given tenofovir in doses resulting in exposures 12 to 50 times higher than the human dose based on body surface area comparisons.

In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to tenofovir in humans have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with tenofovir. The prevalence of birth defects with first-trimester tenofovir exposure was 2.4% (18/756, 95% CI: 1.4%–3.7%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[2]*.

- Placental and breast milk passage
  Studies in rats have demonstrated that tenofovir is secreted in milk. Intravenous administration of tenofovir to pregnant cynomolgus monkeys resulted in a fetal/maternal concentration of 17%, demonstrating that tenofovir does cross the placenta *[3]*. In 3 studies of pregnant women, the cord-to-maternal blood ratio ranged from 0.60 to 0.99, indicating high placental transfer*[4-6]*. In 2 studies including 21 pregnant women receiving tenofovir-based therapy, the cord-to-maternal blood ratio ranged from 0.95 to 0.99 *[4,5]*. There are no data on whether tenofovir is excreted in breast milk in humans.

- Human studies in pregnancy
  Tenofovir pharmacokinetics were evaluated in 19 pregnant women receiving tenofovir-based combination therapy in study P1026s at 30 to 36 weeks gestation and 6 to 12 weeks postpartum *[4]*. The percent of women with tenofovir AUC exceeding the target of 2 μg*hour/mL (the 10th percentile in nonpregnant adults) was lower in women in the third trimester (74%, 14/19) than postpartum (86%, 12/14) (p = 0.02); however, trough levels were similar in the third trimester and postpartum.

  A recent case series found tenofovir to be well tolerated among 76 pregnant women, with 2 stopping therapy, 1 for rash and 1 for nausea. All 78 infants were healthy with no signs of toxicity, and all were HIV-uninfected *[7]*. A retrospective review of 16 pregnancy outcomes among 15 heavily antiretroviral experienced women demonstrated that tenofovir was well-tolerated by the women and associated with normal growth and development in the infants *[8]*.

Zalcitabine (HIVID, ddC) is no longer available in the United States.

Zidovudine (Retrovir, AZT, ZDV) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies

  Zidovudine is mutagenic in 2 *in vitro* assays, clastogenic in 1 *in vitro* and 2 *in vivo* assays, but not cytogenic in a single-dose *in vivo* rat study. Long-term carcinogenicity studies have been performed with zidovudine in mice and rats *[1]*. In mice, 7 late-appearing (after 19 months) vaginal neoplasms (5 nonmetastasizing squamous cell carcinomas, 1 squamous cell papilloma, and 1 squamous polyp) occurred in animals given the highest dose. One late-appearing squamous cell papilloma occurred in the vagina of an animal given an intermediate dose. No vaginal tumors were found at the lowest dose. In rats, 2 late-appearing (after 20 months), nonmetastasizing vaginal squamous cell carcinomas occurred in animals given the highest dose. No vaginal tumors occurred at the low or middle dose in rats. No other drug-related tumors were observed in either sex of either species. At doses that produced tumors in mice and rats, the estimated drug exposure (as measured by AUC) was approximately 3 times (mouse) and 24 times (rat) the estimated human exposure at the recommended therapeutic dose of 100 mg every 4 hours. It is not known how predictive the results of rodent carcinogenicity studies may be for humans.

  Two transplacental carcinogenicity studies were conducted in mice *[2,3]*. One study administered zidovudine at doses of 20 mg/kg/day or 40 mg/kg/day from gestation Day 10 through parturition and lactation with dosing continuing in offspring for 24 months postnatally *[3]*. The doses of zidovudine administered in this study produced zidovudine exposures approximately 3 times the estimated human exposure at recommended doses. After 24 months, an increase in incidence of vaginal tumors was noted with no increase in tumors in the liver or lung or any other organ in either gender. These findings are consistent with results of the standard oral carcinogenicity study in mice, as described earlier. A second study administered zidovudine at maximum tolerated doses of 12.5 mg/day or 25 mg/day (~1,000 mg/kg nonpregnant body weight or ~450 mg/kg of term body weight) to pregnant mice from Days 12 through 18 of gestation *[2]*. There was an increase in the number of tumors in the lung, liver, and female reproductive tracts in the offspring of mice receiving the higher dose level of zidovudine.

- Reproduction/fertility

  Zidovudine, administered to male and female rats at doses up to 7 times the usual adult dose based on body surface area, had no effect on fertility judged by conception rates.

  No effect of zidovudine on reproduction or fertility in rodents has been seen. A dose-related cytotoxic effect on preimplantation mouse embryos can occur, with inhibition of blastocyst and postblastocyst development at zidovudine concentrations similar to levels achieved with human therapeutic doses *[4]*.

- Teratogenicity/developmental toxicity

  Oral teratology studies in the rat and in the rabbit at doses up to 500 mg/kg/day revealed no evidence of teratogenicity with zidovudine. Zidovudine treatment resulted in embryo/fetal toxicity as evidenced by an increase in the incidence of fetal resorptions in rats given 150 or 450 mg/kg/day and rabbits given 500 mg/kg/day. The doses used in the teratology studies resulted in peak zidovudine plasma concentrations (after

one-half of the daily dose) in rats 66 to 226 times, and in rabbits 12 to 87 times, mean steady-state peak human plasma concentrations (after one-sixth of the daily dose) achieved with the recommended daily dose (100 mg every 4 hours). In an *in vitro* experiment with fertilized mouse oocytes, zidovudine exposure resulted in a dose-dependent reduction in blastocyst formation. In an additional teratology study in rats, a dose of 3,000 mg/kg/day (very near the oral median lethal dose in rats of 3,683 mg/kg) caused marked maternal toxicity and an increase in the incidence of fetal malformations. This dose resulted in peak zidovudine plasma concentrations 350 times peak human plasma concentrations (estimated AUC in rats at this dose level was 300 times the daily AUC in humans given 600 mg/day). No evidence of teratogenicity was seen in this experiment at doses of 600 mg/kg/day or less.

Increased fetal resorptions occurred in pregnant rats and rabbits treated with doses of zidovudine that produced drug plasma concentrations 66 to 226 times (rats) and 12 to 87 times (rabbits) the mean steady-state peak human plasma concentration following a single 100-mg dose of zidovudine. There were no other reported developmental anomalies. In another developmental toxicity study, pregnant rats received zidovudine up to near-lethal doses that produced peak plasma concentrations 350 times peak human plasma concentrations (300 times the daily AUC in humans given 600 mg/day zidovudine). This dose was associated with marked maternal toxicity and an increased incidence of fetal malformations. However, there were no signs of teratogenicity at doses up to one-fifth the lethal dose.

In humans, in the placebo-controlled perinatal trial PACTG 076, the incidence of minor and major congenital abnormalities was similar between zidovudine and placebo groups and no specific patterns of defects were seen *[5,6]*. A report from the Women and Infants Transmission Study (WITS), a cohort study enrolling women during pregnancy, described an association between first-trimester exposure to zidovudine and a 10-fold increased risk of hypospadius *[7]*. However, in the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to zidovudine have been monitored to be able to detect at least a 1.5-fold increase in risk of overall birth defects and a 2-fold increase in defects in the more common classes, defects of the cardiovascular and genitourinary systems. No such increase in birth defects has been observed with zidovudine. The prevalence of birth defects with first-trimester zidovudine exposure was 3.1% (97/3,167, 95% CI: 2.5%–3.7%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[8]*.

- Placental and breast milk passage
  Zidovudine rapidly crosses the human placenta, achieving cord-to-maternal blood ratios of about 0.80. Zidovudine is excreted into human breast milk. In 1 study in Kenya in 67 mothers receiving a combination regimen of zidovudine, lamivudine, and nevirapine, zidovudine concentration in the breast milk of mothers averaged 9 ng/mL and the ratio of breast milk to maternal plasma zidovudine concentration averaged 44% *[9]*. No zidovudine was detectable in the plasma of their nursing infants, who only received zidovudine via breast milk.

- Human studies in pregnancy
  Zidovudine is well tolerated in pregnancy at recommended adult doses and in the full-term neonate at 2 mg/kg body weight orally every 6 hours *[5,10]*. Long-term data on the safety of *in utero* drug exposure in humans are not available for any antiretroviral drug; however, short-term data on the safety of zidovudine are reassuring. No difference in disease progression between women in PACTG 076 who received zidovudine and those who received placebo has been seen in follow-up through 4 years postpartum *[11]*. Infants with *in utero* zidovudine exposure followed for nearly 6 years have shown no significant differences from those who received placebo in immunologic, neurologic, and growth parameters*[6,12]*; follow-up of these infants is continuing.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

For information regarding potential interaction of the non-nucleoside reverse transcriptase inhibitor drug class and methergine, see **Postpartum Hemorrhage, Antiretroviral Drugs, and Methergine Use** in the Perinatal Guidelines. For more information regarding nevirapine hepatic/rash toxicity, see **Nevirapine and Hepatic/Rash Toxicity** in the Perinatal Guidelines.

Delavirdine (Rescriptor, DLV) is no longer available in the United States.

Efavirenz (Sustiva, EFV) is classified as FDA pregnancy category D.

- Animal carcinogenicity studies
  Efavirenz was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Long-term animal carcinogenicity studies with efavirenz in mice and rats have been completed. At systemic drug exposures approximately 1.7-fold higher than in humans receiving standard therapeutic doses, no increase in tumor incidence above background was observed in male mice but an increase in hepatocellular adenomas and carcinomas and pulmonary alveolar/bronchiolar adenomas above background were found in

female mice. In male and female rats administered systemic drug exposures lower than that in humans receiving therapeutic doses, no increase in tumor incidence above background was observed.

- Reproduction/fertility animal studies
  No effect of efavirenz on reproduction or fertility in rodents has been seen.

- Teratogenicity/developmental toxicity
  An increase in fetal resorptions was observed in rats at efavirenz doses that produced peak plasma concentrations and AUC values in female rats equivalent to or lower than those achieved in humans at the recommended human dose (600 mg once daily). Efavirenz produced no reproductive toxicities when given to pregnant rabbits at doses that produced peak plasma concentrations similar to and AUC values approximately half of those achieved in humans administered efavirenz (600 mg once daily). Central nervous system (CNS) malformations were observed in 3 of 20 infants born to pregnant cynomolgus monkeys receiving efavirenz from gestational Days 20 to 150 at a dose of 30 mg/kg twice daily (resulting in plasma concentrations comparable to systemic human therapeutic exposure) *[1]*. The malformations included anencephaly and unilateral anophthalmia in 1 fetus, microphthalmia in another fetus, and cleft palate in a third fetus.

  In prospectively reported pregnancies with exposure to efavirenz-based regimens in the Antiretroviral Pregnancy Registry through July 2009, birth defects were observed in 14 (2.8%) of 501 (95% CI: 1.5%–4.7%) live births with first-trimester exposure. Defects reported prospectively after first-trimester efavirenz exposure included a case of sacral aplasia, myelomeningocele, and hydrocephalus with fetal alcohol syndrome and a case of bilateral facial clefts, anophthalmia, and amniotic band *[2]*. Other defects reported included polydactyly (3 cases), hydronephrosis, bilateral hip dislocation and umbilical hernia, bilateral hip dislocation, urinary obstruction with duplicated right collecting system, long bone malformation, shortening of right leg, cutis aplasia, hip dysplasia with pulmonary stenosis, and unspecified heart anomaly. In retrospective case reports, there are 6 reports of central nervous system defects, including 3 cases of meningomyelocele in infants born to mothers receiving efavirenz during the first trimester [Bristol-Myers Squibb April 14 2010, De Santis M, Arch Intern Med, 2002; Fundaro C, AIDS, 2002]. Although a causal relationship of these events to the use of efavirenz has not been established, similar defects have been observed in preclinical studies of efavirenz.

- Placental and breast milk passage
  Efavirenz crosses the placenta in rats, rabbits, and primates, producing cord blood concentrations similar to concentrations in maternal plasma. In a study of 13 women in Rwanda, efavirenz was given during the last trimester of pregnancy and for 6 months after delivery *[6]*. Efavirenz concentrations were measured in maternal plasma, breast milk, and infant plasma. Efavirenz passed into breast milk with a ratio of 0.54 (mean breast milk to mean maternal plasma concentration) and 4.08 (mean skim milk to mean newborn plasma concentration). Mean infant plasma efavirenz concentrations were 13.1% of maternal plasma levels. No data about efavirenz in neonates are currently available.

- Human studies in pregnancy
  Limited data on use of efavirenz in pregnancy are available. In 1 study of 71 pregnancies occurring among women in a primary therapy study, the rate of early losses and stillbirths did not differ among women on efavirenz or other drugs *[7]*. Among 22 livebirths to women exposed to efavirenz in the first trimester, 1 (4.5%) infant had an abnormality, right limb shortening.

  Efavirenz is classified as FDA Pregnancy Category D and may cause fetal harm when administered to a pregnant woman during the first trimester. Because of the potential for teratogenicity, pregnancy should be avoided in women receiving efavirenz, and treatment with efavirenz should be avoided during the first trimester, which is the primary period of fetal organogenesis. Women of childbearing potential should undergo pregnancy testing prior to initiation of efavirenz and should be counseled about the potential risk to the fetus and need to avoid pregnancy. Different types of contraception have known failure rates in women not receiving antiretroviral drugs; these failure rates may increase with drug interactions between estrogen-progesterone hormonal contraceptives and some antiretroviral drugs, including efavirenz. Alternate

antiretroviral regimens that do not include efavirenz should be strongly considered in women who are planning to become pregnant or who are sexually active and not using effective contraception. Barrier contraception should always be used in combination with other methods of contraception (e.g., hormonal contraceptives, intrauterine device). A study evaluating the interaction between efavirenz and depomedroxyprogesetrone (DMPA) in 17 women found no change in the pharmacokinetic profile of either efaviraenz or DMPA with concomitant use *[8]*. DMPA levels remained above the level needed for inhibition of ovulation throughout the dosing interval.

Etravirine (Intelence, ETV) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Etravirine was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Carcinogenicity studies of etravirine in rodents are ongoing.

- Reproduction/fertility
  No effect on fertility and early embryonic development was observed when etravirine was tested in rats at maternal doses up to 500 mg/kg/day, resulting in systemic drug exposure equivalent to the recommended human dose (400 mg/day).

- Teratogenicity/developmental toxicity
  Animal reproduction studies in rats and rabbits at systemic exposures equivalent to those at the recommended human dose of 400 mg/day revealed no evidence of fetal toxicity or altered development. Developmental toxicity studies were performed in rabbits (at oral doses up to 375 mg/kg/day) and rats (at oral doses up to 1,000 mg/kg/day). In both species, no treatment-related embryo-fetal effects including malformations were observed. In addition, no treatment effects were observed in a separate pre- and postnatal study performed in rats at oral doses up to 500 mg/kg/day. The systemic exposures achieved in these animal studies were equivalent to those at the recommended human dose (400 mg/day).

- Placental and breast milk passage
  There are no data on whether etravirine crosses the placenta or is excreted in breast milk in humans.

- Human studies in pregnancy
  No adequate and well-controlled studies of etravirine use in pregnant women have been conducted. In addition, no pharmacokinetic studies have been conducted in pregnant patients.

Nevirapine (Viramune, NVP) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Nevirapine showed no evidence of mutagenic or clastogenic activity in a battery of *in vitro* and *in vivo* studies. Hepatocellular adenomas and carcinomas were increased at all doses in male mice and rats, and at higher doses in female mice and rats. Systemic exposure at all doses studied was lower than systemic exposure in humans receiving therapeutic nevirapine doses. Given the lack of genotoxic activity of nevirapine, the relevance to humans of hepatocellular neoplasms in nevirapine-treated mice and rats is not known.

- Reproduction/fertility
  Evidence of impaired fertility was seen in female rats at nevirapine doses providing systemic exposure comparable to human therapeutic exposure.

- Teratogenicity/developmental toxicity
  Teratogenic effects of nevirapine have not been observed in reproductive studies with rats and rabbits at systemic exposures approximately equivalent to or 50% greater than the recommended human dose (based on AUC). In rats, however, a significant decrease in fetal weight occurred at doses producing systemic concentrations approximately 50% higher than human therapeutic exposure.

  In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposure to nevirapine in humans have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with nevirapine. The prevalence of birth defects with first-trimester nevirapine exposure was 2.1% (18/842, 95% CI: 1.3%–3.4 %) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*.

- Placental and breast milk passage
  Nevirapine crosses the placenta and achieves neonatal blood concentrations equivalent to that in the mother (cord-to-maternal blood ratio approximately 0.90) *[2]*. Nevirapine is excreted into human breast milk; the median concentration in 4 breast milk samples obtained from 3 women during the first week after delivery was approximately 76% (range 54%–104%) of serum levels *[2]*. In 19 women receiving combination therapy with nevirapine, lamivudine, and zidovudine, breast milk nevirapine concentration was 6,795 ng/mL, which was 0.67 times that of maternal serum *[3]*. In a larger study, 67 HIV-infected nursing mothers receiving a combination regimen of zidovudine, lamivudine, and nevirapine in Kenya; median nevirapine breast milk concentration was 4,564 ng/mL *[4]*. Their infants, who only received nevirapine via breast milk, had a median nevirapine concentration of 734 ng/mL.

- Human studies in pregnancy

  Short-Term Peripartum Prophylaxis:

  A Phase I study (PACTG 250) evaluated the safety and pharmacokinetics of nevirapine administered to infected pregnant women as a single 200-mg dose at the onset of labor and as a single 2-mg/kg dose to the infant at age 48 to 72 hours *[2]*. No adverse effects were seen in the women or the infants.

Pharmacokinetic parameters in pregnant women receiving intrapartum nevirapine were similar although somewhat more variable than in nonpregnant adults, possibly due to incomplete drug absorption associated with impaired gastrointestinal function during labor. Nevirapine elimination was prolonged in the infants. The regimen maintained serum concentrations associated with antiviral activity in the infants for the first week of life.

The safety, toxicity, and pharmacokinetics of nevirapine were also studied in HIV-infected pregnant women beginning chronic therapy late in the third trimester and their infants *[5]*. Initial dose pharmacokinetic profiles in pregnant women were similar to those seen in nonpregnant adults. Serum nevirapine concentrations fell below the 100 ng/mL target concentration by Day 7 of life in 4 of 8 infants, suggesting that nevirapine elimination was accelerated in infants whose mother received chronic nevirapine administration compared to newborns whose mothers received only a single intrapartum nevirapine dose.

The HIVNET 012 study in Uganda compared nevirapine (200 mg orally to the mother at the onset of labor and 2 mg/kg to the neonate within 72 hours of birth) to zidovudine (600 mg orally to the mother at the onset of delivery and 300 mg every 3 hours until delivery, and 4 mg/kg orally twice daily for the first 7 days of life to the neonate). In this study, nevirapine lowered the risk of HIV transmission by nearly 50% during the first 14 to 16 weeks of life compared to zidovudine *[6]*. However, the women in this African trial were not receiving any other antiretroviral therapy.

In the United States, most infected women who know their HIV status during pregnancy receive combination antiretroviral therapy, usually including zidovudine, as well as intravenous zidovudine during delivery, with 6 weeks of zidovudine given to their infant. A Phase III perinatal trial (PACTG 316) conducted in the United States, Europe, the Bahamas, and Brazil evaluated whether the HIVNET 012 single-dose nevirapine regimen in combination with standard antiretroviral therapy (at minimum the PACTG 076 zidovudine regimen; 77% of women in the trial received combination therapy) would provide additional benefits in reducing transmission. Transmission was not significantly different between those who had the addition of single-dose nevirapine (1.4%) and those who did not (1.6%) *[7]*.

Nevirapine resistance can be induced by a single mutation. As a result of its long half-life, nevirapine can be detected in plasma up to 3 weeks after administration of a single intrapartum dose *[8]*. This period of persistent subtherapeutic drugs levels exerts selective pressure that predisposes to the development of resistant strains of HIV *[9]*. Nevirapine resistance mutations were detected at 6 weeks postpartum in 19% of antiretroviral-naïve women in HIVNET 012 and 15% of a subset of women receiving additional antiretroviral drugs during pregnancy in PACTG 316 who received single-dose nevirapine during labor *[10-11]*. The clinical implications of the presence of nevirapine-resistant HIV are unclear. In HIVNET 012, these mutations were no longer detectable in plasma virus in women at 13 to 18 months postpartum *[12]*. Evaluation at later time points was not done in PACTG 316. Single-dose nevirapine appears to be as effective in preventing HIV transmission in subsequent pregnancies as when it is used for the first time*[13-14]*. Several studies have suggested that there is no decrease in efficacy when nevirapine-based combination therapy is started at least 6 to 12 months after delivery*[15-18]*. Administration of postpartum antiretrovirals to the mother can reduce the frequency of detection of nevirapine-resistant strains*[9, 19-21]*.

Longer Term Antenatal Combination Therapy:

The pharmacokinetics of nevirapine have been evaluated in pregnant women receiving nevirapine as part of combination antiretroviral therapy during pregnancy. A study that determined nevirapine pharmacokinetics in 26 women during pregnancy (7 second trimester, 19 third trimester) and again in the same women 4 to 12 weeks after delivery found that pregnancy did not alter nevirapine pharmacokinetic parameters *[22]*. In contrast, in nevirapine pharmacokinetic data from a therapeutic drug monitoring program that included 12-hour sampling, nevirapine clearance was 20% greater, AUC was 28% lower, and C_{max} was 30% lower in 16 pregnant women compared to 13 nonpregnant women *[23]*.

Severe, life-threatening, and in some cases, fatal hepatotoxicity, including fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure, and severe, life-threatening hypersensitivity skin reactions, including Stevens-Johnson syndrome, have been reported in HIV-infected patients receiving nevirapine in combination with other drugs for treatment of HIV disease and in a small number of individuals receiving nevirapine as part of a combination regimen for post-exposure prophylaxis of nosocomial or sexual HIV exposure *[24]*. These toxicities have not been reported in women or infants receiving two-dose nevirapine (the HIVNET 012 regimen) for prevention of perinatal transmission. The greatest risk of severe rash or hepatic events occurs during the first 6 to 18 weeks of therapy, although the risk of toxicity continues past this period and monitoring should continue at frequent intervals.

The development of severe nevirapine-associated skin rash has been reported to be 5.5 to 7.3 times more common in women than men, and has been reported in pregnant women *[25-27]*. Other studies have found that hepatic adverse events with systemic symptoms (often rash) were 3.2-fold more common in women than men *[28]*. The degree of risk of hepatic toxicity varies with CD4 cell count. In a summary analysis of data from 17 clinical trials of nevirapine therapy, women with CD4 counts >250 cells/mm^3 were 9.8 times more likely than women with lower CD4 counts to experience symptomatic, often rash-associated, nevirapine-related hepatotoxicity *[28]*. Higher CD4 cell counts have also been associated with increased risk of severe nevirapine-associated skin rash *[26]*. In controlled clinical trials, clinical hepatic events, regardless of severity, occurred in 4.0% (range 2.5% – 11.0%) of patients who received nevirapine; however, the risk of nevirapine-associated liver failure or hepatic mortality has been lower, in the range of 0.04%–0.40% *[28-29]*. Severe or life-threatening rash occurs in approximately 2% of patients receiving nevirapine *[29]*.

Although deaths due to hepatic failure have been reported in HIV-infected pregnant women receiving nevirapine as part of a combination antiretroviral regimen, it is unknown if pregnancy increases the risk of hepatotoxicity in women receiving nevirapine or other antiretroviral drugs *[30-31]*. In an analysis of two multi-center prospective cohorts, pregnancy itself was a risk factor for liver enzyme elevations (RR 4.7; 95% CI: 3.4–6.5), although nevirapine use was not, regardless of pregnancy status *[32]*. Further data from the same cohorts did not show any increased risk of hepatotoxicity in HIV-infected pregnant women receiving nevirapine-based combination antiretroviral therapy versus non-nevirapine-based combination antiretroviral therapy *[33]*. These data suggest that nevirapine is no more toxic in pregnant women than in nonpregnant women. Women initiating nevirapine with CD4 counts >250 cells/mm^3, including pregnant women receiving antiretroviral drugs solely for prevention of transmission, have an increased risk of developing symptomatic, often rash-associated, nevirapine-related hepatotoxicity, which can be severe, life-threatening, and in some cases fatal *[34]*. Nevirapine should therefore be used as a component of a combination regimen in this setting only if the benefit clearly outweighs the risk. Women with CD4 counts less than 250/mm^3 can receive nevirapine-based regimens, and women who enter pregnancy on nevirapine regimens and are tolerating the regimens well may continue therapy, regardless of CD4 count. Hepatic toxicity has not been seen in women receiving single-dose nevirapine during labor for prevention of perinatal transmission of HIV.

Because pregnancy itself can mimic some of the early symptoms of hepatotoxicity, health care providers caring for women receiving nevirapine during pregnancy should be aware of this potential complication and conduct frequent and careful monitoring of clinical symptoms and hepatic transaminases (i.e., alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), particularly during the first 18 weeks of therapy. Some clinicians measure serum transaminases at baseline, every 2 weeks for the first month, monthly through 4 months, and every 1 to 3 months thereafter (**Adult Antiretroviral Guidelines**); in patients with pre-existing liver disease, monitoring should be performed more frequently when initiating therapy and then monthly *[35]*. Transaminase levels should be checked in all women who develop a rash while receiving nevirapine. Patients who develop suggestive clinical symptoms accompanied by elevation in serum transaminase levels (ALT and/or AST) or have asymptomatic but severe transaminase elevations should stop nevirapine and not receive nevirapine therapy in the future.

PROTEASE INHIBITORS

For information regarding the protease inhibitor (PI) class of drugs and potential metabolic complications during pregnancy and pregnancy outcome, see **Protease Inhibitor Therapy and Hyperglycemia** and **Combination Antiretroviral Therapy and Pregnancy Outcome** in the Perinatal Guidelines.

Amprenavir (Agenerase, APV) is no longer available in the United States.

Atazanavir (Reyataz, ATV) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  In *in vitro* and *in vivo* assays, atazanavir shows evidence of clastogenicity but not mutagenicity. Two-year carcinogenicity studies in mice and rats were conducted with atazanavir. In female mice, the incidence of benign hepatocellular adenomas was increased at systemic exposures 7.2-fold higher than those in humans at the recommended therapeutic dose (400 mg once daily). There were no increases in the incidence of tumors in male mice at any dose. In rats, no significant positive trends in the incidence of neoplasms occurred at systemic exposures up to 5.7-fold higher than those in humans at the recommended therapeutic dose.

- Reproduction/fertility
  No effect of atazanavir on reproduction or fertility in male and female rodents was seen at systemic drug exposures (AUC up to 2 times those achieved in humans at the recommended therapeutic dose).

- Teratogenicity/developmental toxicity
  Atazanavir did not produce teratogenic effects in rabbits with maternal dosing producing systemic drug exposure equivalent to (rabbits) or 2-times that (rats) achieved in humans at the recommended therapeutic dose (400 mg once daily). In developmental toxicity studies in rats, maternal dosing that resulted in maternal toxicity and produced systemic drug exposure 2-times the human exposure also resulted in weight loss or suppression of weight gain in the offspring. However, offspring were unaffected at lower maternal doses that produced systemic drug exposure equivalent to that observed in humans at the recommended therapeutic dose.

  In a retrospective analysis from London of atazanavir used in 31 women during 33 pregnancies (20 of whom were receiving atazanavir at conception), there were 2 miscarriages at 12 and 16 weeks, 26 infants born, and 5 women still pregnant *[1]*. No infant required phototherapy and no birth defects were seen; none of the infants were HIV infected. In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposure to atazanavir in humans have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with atazanavir. The prevalence of birth defects with first-trimester atazanavir exposure was 2.6% (9/343, 95% CI: 1.2%–4.9%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[2]*.

  Elevation in indirect (unconjugated) bilirubin attributable to atazanavir-related inhibition of hepatic uridine diphosphate glucuronosyltransferase enzyme occurs frequently during treatment with atazanavir. Studies have demonstrated that infants born to mothers who received atazanavir during pregnancy do not have pathologic or dangerous bilirubin elevations in the newborn period *[1,3-5]*.

- Placental and breast milk passage
  In studies of women receiving atazanavir/ritonavir-based combination therapy during pregnancy, cord blood atazanavir concentration averaged 13%–16% of maternal serum levels at delivery *[3,5]*. Atazanavir is excreted in the milk of lactating rats. In a small study of 3 women, the median ratio of breast milk atazanavir concentration to that in plasma was 13% *[6]*.

- Human studies in pregnancy
  The pharmacokinetics of atazanavir 300 mg when administered once daily during pregnancy with ritonavir 100 mg have been investigated in 4 studies. In a retrospective study, trough atazanavir concentrations were measured in 19 pregnant women at a median of 30 weeks gestation (14 in third trimester); all but 2 women had a trough atazanavir concentration greater than 100 ng/mL *[1]*. Full pharmacokinetic profiles of atazanavir when administered daily as 300 mg with 100 mg ritonavir during pregnancy have been evaluated in 3 studies. In a study of 17 pregnant women, atazanavir AUC was not different during pregnancy compared to 1–6 months postpartum (28.5 µg*hr/mL vs. 30.5 µg*hr/mL, respectively) *[3]*. In contrast, another study determined atazanavir pharmacokinetics in 12 pregnant women and found reductions in atazanavir concentrations of more than 50% during pregnancy, with a mean AUC of 26.6 µg*hr/mL during the third trimester compared to 57.0 µg*hr/mL at 4 weeks postpartum. All subjects had trough atazanavir concentrations greater than 150 ng/mL *[4]*. Similar results were found in another study of atazanavir pharmacokinetics in 18 women not receiving tenofovir, with median AUC of 41.9 µg*hr/mL during pregnancy versus 58.0µ g*hr/mL at 6–12 weeks postpartum *[5]*. Atazanavir AUC was further reduced in 15 women also receiving tenofovir, with median AUC of 30.5 µg*hr/mL during pregnancy compared to 44.1 µg*hr/mL postpartum. Mean atazanavir AUC in nonpregnant adults receiving 300 mg plus 100 mg ritonavir daily dosing is 57.0 µg*hr/mL and is reduced by about 25% in adults receiving concomitant tenofovir *[7,8]*. Investigations of atazanavir exposure with the use of an increased dose of 400 mg in combination with 100 mg ritonavir during pregnancy are under way.

Darunavir (Prezista, DRV) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Darunavir was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. A dose-related increase in the incidence of hepatocellular adenomas and carcinomas was observed in males and females of both mice and rats as well as an increase in thyroid follicular cell adenomas in male rats. The observed hepatocellular findings in rodents are considered to be of limited relevance to humans. Repeated administration of darunavir to rats caused hepatic microsomal enzyme induction and increased thyroid hormone elimination, which predispose rats, but not humans, to thyroid neoplasms. At the highest tested doses, the systemic exposures to darunavir (based on AUC) were between 0.4- and 0.7-fold (mice) and 0.7- and 1-fold (rats) of those observed in humans at the recommended therapeutic doses (600/100 mg twice daily or 800/100 mg once daily).
- Reproduction/fertility
  No effects on fertility and early embryonic development were seen with darunavir in rats.
- Teratogenicity/developmental toxicity
  No embryotoxicity or teratogenicity was seen in mice, rats, or rabbits. Because of limited bioavailability of darunavir in animals and dosing limitation, the plasma exposures were approximately 50% (mice and rats) and 5% (rabbits) of those obtained in humans. In the rat pre- and postnatal development study, a reduction in pup weight gain was observed with darunavir alone or with ritonavir during lactation due to exposure of pups to drug substances via the milk. In juvenile rats single doses of darunavir (20 mg/kg to 160 mg/kg at ages 5 to 11 days) or multiple doses of darunavir (40 mg/kg to 1,000 mg/kg at age 12 days) caused mortality. The mortalities were associated with convulsions in some of the animals. Within this age range, exposures in

plasma, liver, and brain were dose and age dependent and were considerably greater than those observed in adult rats. These findings were attributed to the ontogeny of the CYP450 liver enzymes involved in the metabolism of darunavir and the immaturity of the blood-brain barrier. Sexual development, fertility, or mating performance of offspring were not affected by maternal treatment. No data are available in humans.

- Placental and breast milk passage
  No animal studies of placental passage of darunavir have been reported. As noted above, passage of darunavir into breast milk has been noted in rats. It is unknown if placental or breast milk passage of darunavir occurs in humans.
- Human studies in pregnancy
  No studies of darunavir have been conducted in pregnant women or neonates. Darunavir is not recommended for children younger than 3 years.

Fosamprenavir (Lexiva, f-APV) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Fosamprenavir and amprenavir were neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Carcinogenicity studies of fosamprenavir showed an increase in the incidence of hepatocellular adenomas and hepatocellular carcinomas at all doses tested in male mice and at the highest dose tested in female mice. In rats, the incidence of hepatocellular adenomas and thyroid follicular cell adenomas in males (all doses tested) and in females (two highest doses tested) was also increased. Repeat dose studies in rats produced effects consistent with enzyme activation, which predisposes rats, but not humans, to thyroid neoplasms. In rats only there was an increase in interstitial cell hyperplasia at higher doses and an increase in uterine endometrial adenocarcinoma at the highest dose tested. The incidence of endometrial findings was slightly increased over concurrent controls but was within background range for female rats. Thus the relevance of the uterine endometrial adenocarcinomas is uncertain. Exposures in the carcinogenicity studies were 0.3- to 0.7-fold (mice) and 0.7- to 1.4-fold (rats) those in humans given 1,400 mg twice daily of fosamprenavir alone, and 0.2- to 0.3-fold (mice) and 0.3- to 0.7-fold (rats) those in humans given 1,400 mg once daily of fosamprenavir plus 200 mg ritonavir once daily or 0.1- to 0.3-fold (mice) and 0.3- to 0.6-fold (rats) those in humans given 700 mg of fosamprenavir plus 100 mg ritonavir twice daily.
- Reproduction/fertility
  No impairment of fertility or mating was seen in rats at doses providing 3 to 4 times the human exposure to fosamprenavir alone or exposure similar to that with fosamprenavir and ritonavir dosing in humans. No affect was seen on the development or maturation of sperm in rats at these doses.
- Teratogenicity/developmental toxicity
  Fosamprenavir was studied in rabbits at 0.8 and in rats at 2 times the exposure in humans to fosamprenavir alone and at 0.3 (rabbits) and 0.7 (rats) times the exposure in humans to the combination of fosamprenavir and ritonavir. In rabbits administered fosamprenavir (alone or in combination) the incidence of abortion was increased. In contrast, administration of amprenavir at a lower dose in rabbits was associated with abortions and an increased incidence of minor skeletal variations from deficient ossification of the femur, humerus, and trochlea. Fosamprenavir administered to pregnant rats (at 2 times human exposure) was associated with a reduction in pup survival and body weights in rats. F1 female rats had an increased time to successful mating, an increased length of gestation, a reduced number of uterine implantation sites per litter, and reduced gestational body weights compared to controls.
- Placental and breast milk passage
  It is unknown whether fosamprenavir crosses the placenta. Amprenavir is excreted in the milk of lactating rats; it is not known if it is excreted in human milk.

- Human studies in pregnancy
  There are very limited data on fosamprenavir in pregnant women. There is a pediatric liquid formulation approved for children older than 2 years of age, but there is no dosing information for neonates.

Indinavir (Crixivan, IDV) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  There is no evidence that indinavir is mutagenic or clastogenic in both *in vitro* and *in vivo* assays. No increased incidence of any tumor types occurred in long-term studies in mice. At the highest dose studied in rats (640 mg/kg/day or 1.3-fold higher than systemic exposure at human therapeutic doses), thyroid adenomas were seen in male rats.
- Reproduction/fertility
  No effect of indinavir has been seen on reproductive performance, fertility, or embryo survival in rats.
- Teratogenicity/developmental toxicity
  There has been no evidence of teratogenicity or treatment-related effects on embryonic/fetal survival or fetal weights of indinavir in rats, rabbits, or dogs at exposures comparable to or slightly greater than therapeutic human exposure. In rats, developmental toxicity manifested by an increase in supernumerary and cervical ribs was observed at doses comparable to those administered to humans. No treatment-related external or visceral changes were observed in rats. No treatment-related external, visceral, or skeletal changes were seen in rabbits (fetal exposure limited, approximately 3% of maternal levels) or dogs (fetal exposure approximately 50% of maternal levels). Indinavir was administered to Rhesus monkeys during the third trimester of pregnancy (at doses up to 160 mg/kg twice daily) and to neonatal Rhesus monkeys (at doses up to 160 mg/kg twice daily). When administered to neonates, indinavir caused an exacerbation of the transient physiologic hyperbilirubinemia seen in this species after birth; serum bilirubin values were approximately 4-fold greater than controls at 160 mg/kg twice daily. A similar exacerbation did not occur in neonates after *in utero* exposure to indinavir during the third trimester of pregnancy. In Rhesus monkeys, fetal plasma drug levels were approximately 1% – 2% of maternal plasma drug levels approximately 1 hour after maternal dosing at 40, 80, or 160 mg/kg twice daily.

  In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposure to indinavir in humans have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with indinavir The prevalence of birth defects with first-trimester indinavir exposure was 2.2% (6/276, 95% CI: 0.8%–4.7%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*.
- Placental and breast milk passage
  Significant placental passage of indinavir occurs in rats and dogs, but only limited placental transfer occurs in rabbits. In a Phase I study in pregnant women and their infants (PACTG 358, see below), transplacental passage of indinavir was minimal *[2]*. Additionally, in a study of cord blood samples from 21 women treated with indinavir during pregnancy, the cord blood concentration of indinavir was less than the assay limit of detection in samples from all women *[3]*. Indinavir is excreted in the milk of lactating rats at concentrations slightly greater than maternal levels (milk-to-plasma ratio 1.26 to 1.45); it is not known if indinavir is excreted in human milk.
- Human studies in pregnancy
  The optimal dosing regimen for use of indinavir in pregnant patients has not been established. A Phase I/II safety and pharmacokinetic study (PACTG 358) of indinavir (800 mg three times a day) in combination with zidovudine and lamivudine in pregnant HIV-infected women and their infants was conducted *[2]*. The mean indinavir plasma $AUC_{0\text{-}8hr}$ at weeks 30 to 32 of gestation (n =11) was 74% (95% CI: 50%–86%) lower than that observed 6 weeks postpartum. The pharmacokinetics of indinavir in these 11 patients at 6 weeks postpartum were generally similar to those observed in nonpregnant patients in another study. In another study, 2 pregnant HIV-infected women receiving combination therapy including indinavir (800 mg three

times a day) had significantly reduced AUC indinavir exposures in the third trimester compared to postpartum evaluations (52% and 86% respectively) *[4]*. Therefore, given the substantially lower antepartum exposures observed in these studies and the generally limited data in this patient population, use of indinavir as a sole PI is not recommended in HIV-infected pregnant patients.

Two studies have evaluated indinavir used in conjunction with low-dose ritonavir in twice-daily dosing. The first evaluated 2 women whose regimen included indinavir 800 mg twice daily with ritonavir 200 mg twice daily. Both women achieved third-trimester AUC indinavir levels greater than those for historical nonpregnant controls *[4]*. A more recent study evaluated use of combination therapy including indinavir 400 mg twice daily with ritonavir 100 mg twice daily. Data are available for 28 women, 23 (82%) of whom had C_{trough} values above the targeted cutoff of 120 ng/mL. Of the 5 women with low C_{trough} values, 3 had undetectable HIV RNA viral loads at delivery *[5]*. Based on these data, indinavir may be used in pregnancy with ritonavir boosting. Given the limited data on appropriate dosing, HIV RNA levels and, potentially, trough drug levels should be monitored during indinavir use in pregnancy.

Antiretroviral therapy with a twice-daily regimen containing 400 milligrams of indinavir and 100 milligrams of ritonavir in human immunodeficiency virus type 1-infected women during pregnancy. *Antimicrob Agents Chemother*, 2008. 52(4):1542-4. http://www.ncbi.nlm.nih.gov/pubmed/18250187

Lopinavir + Ritonavir (Kaletra, LPV/r) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Neither lopinavir nor ritonavir was found to be mutagenic or clastogenic in a battery of *in vitro* and *in vivo* assays. Lopinavir/ritonavir combination was evaluated for carcinogenic potential by oral gavage administration to mice and rats for up to 104 weeks. Results showed an increase in the incidence of benign hepatocellular adenomas and an increase in the combined incidence of hepatocellular adenomas plus carcinoma in both males and females in mice and males in rats at doses that produced approximately 1.6 to 2.2 times (mice) and 0.5 times (rats) the human exposure at the recommended therapeutic dose of 400 mg/100 mg (based on AUC_{0-24hr} measurement). Administration of lopinavir/ritonavir did not cause a statistically significant increase in the incidence of any other benign or malignant neoplasm in mice or rats.
- Reproduction/fertility
  Lopinavir in combination with ritonavir at a 2:1 ratio produced no effects on fertility in male and female rats with exposures approximately 0.7-fold for lopinavir and 1.8-fold for ritonavir of the exposures in humans at the recommended therapeutic dose.
- Teratogenicity/developmental toxicity
  There has been no evidence of teratogenicity with administration of lopinavir + ritonavir to pregnant rats or rabbits. In rats treated with a maternally toxic dosage (100 mg lopinavir/50 mg ritonavir/kg/day), embryonic and fetal developmental toxicities (early resorption, decreased fetal viability, decreased fetal body weight,

increased incidence of skeletal variations, and skeletal ossification delays) were observed. Drug exposure in the pregnant rats was 0.7-fold for lopinavir and 1.8-fold for ritonavir of the exposures in humans at the recommended therapeutic dose. In a peri- and postnatal study in rats, a decrease in survival of pups between birth and postnatal Day 21 occurred with exposures of 40 mg lopinavir/20 mg ritonavir/kg/day or greater. In rabbits, no embryonic or fetal developmental toxicities were observed with a maternally toxic dosage, where drug exposure was 0.6-fold for lopinavir and 1-fold for ritonavir of the exposures in humans at the recommended therapeutic dose.

In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to lopinavir + ritonavir have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with lopinavir + ritonavir. The prevalence of birth defects with first-trimester lopinavir + ritonavir exposure was 1.7% (95% CI: 0.8%–3.2%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*.

- Placental and breast milk passage
  Lopinavir crosses the human placenta; in a pharmacokinetic study, P1026s, the average ratio of lopinavir concentration in cord blood to maternal plasma at delivery was 0.20±0.13. For ritonavir, data in humans indicate only minimal transplacental passage (see ritonavir). Lopinavir and ritonavir are secreted in the breast milk of lactating rats; it is not known if either drug is excreted in human milk.

- Human studies in pregnancy
  The capsule formulation of lopinavir/ritonavir is no longer available; it has been replaced by a new tablet formulation of lopinavir 200 mg/ritonavir 50 mg that is heat stable and does not have a food requirement.

  In nonpregnant adults, plasma concentrations of lopinavir and ritonavir after administration of two 200/50 mg lopinavir/ritonavir tablets are similar to those achieved with three 133/33 mg lopinavir/ritonavir capsules given with food, although with less pharmacokinetic variability. In a study of 51 pregnant women, plasma trough lopinavir levels during the third trimester were compared among 28 women receiving the capsule and 23 women receiving the tablet formulations at standard dosing. No statistical difference was found between the groups, with a mean lopinavir trough level of 4.86 mg/L (capsule) and 4.57 mg/L (tablets) *[2]*. However, the inter-individual variability was lower with the tablets than the capsules. Five of 28 women (17.8%) in the capsule group and 4 of 23 women (17.4%) in the tablet group had trough levels less than the target (3 mg/L); 7 of the 9 women had HIV RNA levels less than detection at the time of their sampling, and 2 with subtherapuetic levels (0.7 and 2.44 mg/L) had plasma RNA of 83 and 56 copies/mL, respectively, at the time of their sampling.

  P1026s evaluated lopinavir pharmacokinetics following standard dosing with the new lopinavir/ritonavir tablet formulation (2 tablets twice daily) until 30 weeks gestation, followed by an increase to 3 tablets twice daily and return to standard dosing at postpartum hospital discharge. Median AUC was 72 µg*h/mL in 7 women receiving standard dosing during the second trimester, 97 µg*h/mL in 25 women receiving the increased dose during the third trimester, and 129 µg*h/mL in 19 women receiving standard dosing at 2 weeks postpartum. These data suggest that the higher lopinavir/ritonavir dose should be used in third-trimester pregnant women and that it should be considered in second-trimester pregnant women, especially those who are PI-experienced, and that lopinavir/ritonavir can be reduced to standard dosing shortly after delivery *[3]*.

  Once-daily dosing of lopinavir/ritonavir capsules or tablets is not recommended in pregnancy because there are no data to address whether drug levels are adequate with such administration.

Abstract 629. http://www.retroconference.org/2008/PDFs/629.pdf

Nelfinavir (Viracept, NFV) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Nelfinvair was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. However, thyroid follicular cell adenomas and carcinomas were increased over baseline in male rats receiving 300 mg/kg/day or higher (equal to a systemic exposure similar to that in humans at therapeutic doses) and female rats receiving 1,000 mg/kg/day (equal to a systemic exposure 3-fold higher than that in humans at therapeutic doses) of nelfinavir.

- Reproduction/fertility
  No effect of nelfinavir has been seen on reproductive performance, fertility, or embryo survival in rats at exposures comparable to human therapeutic exposure. Additional studies in rats indicated that exposure to nelfinavir in females from midpregnancy through lactation had no effect on the survival, growth, and development of the offspring to weaning. Subsequent reproductive performance of these offspring was also not affected by maternal exposure to nelfinavir.

- Teratogenicity/developmental toxicity
  No evidence of teratogenicity has been observed in pregnant rats at exposures comparable to human exposure and in rabbits with exposures significantly less than human exposure.

  In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to nelfinavir have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with nelfinavir. The prevalence of birth defects with first-trimester nelfinavir exposure was 3.4% (37/1,075, 95% CI: 2.4%–4.7%) compared to total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*.

- Placental and breast milk transfer
  In a Phase I study in pregnant women and their infants (PACTG 353, see below), transplacental passage of nelfinavir was minimal *[2]*. Additionally, in a study of cord blood samples from 38 women who were treated with nelfinavir during pregnancy, the cord blood nelfinavir concentration was less than the assay limit of detection in 24 (63%), and the cord blood concentration was low (median, 0.35 µg/mL) in the remaining 14 women *[3]*. Nelfinavir is excreted in the milk of lactating rats; it is not known if it is excreted in human milk.

- Human studies in pregnancy
  A Phase I/II safety and pharmacokinetic study (PACTG 353) of nelfinavir in combination with zidovudine and lamivudine was conducted in pregnant HIV-infected women and their infants *[2]*. Nelfinavir administered at a dose of 750 mg three times daily produced drug exposures in the first nine pregnant HIV-infected women enrolled in the study that were variable and generally lower than those reported in nonpregnant adults for both two and three times daily dosing. Therefore, the study was modified to evaluate an increased dose of nelfinavir given twice daily (1,250 mg twice daily), which resulted in adequate levels of nelfinavir in pregnancy. However, in another study of pregnant women in their second and third trimester dosed at 1,250 mg given twice daily, women in the third trimester had lower concentration of nelfinavir than women in their second trimester and lower concentration than in nonpregnant women *[4]*.

  In a pharmacokinetic study of combination therapy including the new nelfinavir 625-mg tablet formulation (given as 1,250 mg twice daily) in 25 women at 30 to 36 weeks gestation (and 12 also at 6 to 12 weeks

postpartum), peak levels and AUC were lower in the third trimester than postpartum *[5]*. Only 16% (4/25) of women during the third trimester and 8% (1/12) women postpartum had trough values greater that the suggested minimum trough of 800 ng/mL; however, viral load was <400 copies/mL in 96% of women in the third trimester and 86% postpartum.

In September 2007, the manufacturer of nelfinavir (Viracept) in the United States (Pfizer) sent a letter to providers regarding the presence of low levels of ethyl methane sulfonate (EMS), a process-related impurity, in nelfinavir. EMS is teratogenic, mutagenic, and carcinogenic in animals, although no data from humans exist and no increase in birth defects has been observed in the Antiretroviral Pregnancy Registry. Health care providers were advised not to initiate antiretroviral regimens containing Viracept (nelfinavir) in their pregnant female or new pediatric patients and to switch pregnant patients receiving Viracept (nelfinavir) to an alternative therapy unless no alternative was available. As of March 31, 2008, all Viracept (nelfinavir) manufactured and released by Pfizer now meets the new final EMS limits established by the FDA for prescribing to all patient populations, including pregnant women and pediatric patients. Viracept (nelfinavir) may now be prescribed for pregnant women as an alternate PI for women receiving antiretroviral therapy during pregnancy solely for prevention of mother-to-child transmission.

Ritonavir (Norvir, RTV) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Ritonavir was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Carcinogenicity studies in mice and rats have been completed. In male mice, at levels of 50, 100, or 200 mg/kg/day, a dose-dependent increase in adenomas of the liver and combined adenomas and carcinomas of the liver was observed; based on AUC, exposure in male mice at the highest dose was approximately 0.3-fold that in male humans at the recommended therapeutic dose. No carcinogenic effects were observed in female mice with exposures 0.6-fold that of female humans at the recommended therapeutic dose. No carcinogenic effects were observed in rats at exposures up to 6% of recommended therapeutic human exposure.
- Reproduction/fertility
  No effect of ritonavir has been seen on reproductive performance or fertility in rats at drug exposures 40% (male) and 60% (female) of that achieved with human therapeutic dosing; higher doses were not feasible due to hepatic toxicity in the rodents.
- Teratogenicity/developmental toxicity
  No ritonavir-related teratogenicity has been observed in rats or rabbits. Developmental toxicity was observed in rats, including early resorptions, decreased body weight, ossification delays, and developmental variations

such as wavy ribs and enlarged fontanelles; however, these effects occurred only at maternally toxic dosages (exposure equivalent to 30% of human therapeutic exposure). In addition, a slight increase in cryptorchidism was also noted in rats at exposures equivalent to 22% of the human therapeutic dose. In rabbits, developmental toxicity (resorptions, decreased litter size, and decreased fetal weight) was observed only at maternally toxic doses (1.8 times human therapeutic exposure based on body surface area).

In the Antiretroviral Pregnancy Registry, sufficient numbers of first-trimester exposures to ritonavir have been monitored to be able to detect at least a 2-fold increase in risk of overall birth defects. No such increase in birth defects has been observed with ritonavir. The prevalence of birth defects with first-trimester ritonavir exposure was 2.2% (22/1,000, 95% CI: 1.4%–3.3%) compared with total prevalence of birth defects in the U.S. population based on CDC surveillance of 2.7% *[1]*.

- Placental and breast milk transfer
  Transplacental passage of ritonavir has been observed in rats with fetal tissue to maternal serum ratios >1.0 at 24 hours post-dose in mid- and late-gestation fetuses. In a human placental perfusion model, the clearance index of ritonavir was very low, with little accumulation in the fetal compartment and no accumulation in placental tissue *[2]*. In a Phase I study in pregnant women and their infants (PACTG 354, see below), transplacental passage of ritonavir was minimal *[3]*. Additionally, in a study of cord blood samples from six women treated with ritonavir during pregnancy, the cord blood concentration was less than the assay limit of detection in 83%, and was only 0.38 µg/mL in the remaining woman *[4]*. Ritonavir is excreted in the milk of lactating rats; it is unknown if it is excreted in human milk.
- Human studies in pregnancy
  A Phase I/II safety and pharmacokinetic study (PACTG 354) of ritonavir in combination with zidovudine and lamivudine in pregnant HIV-infected women and their infants showed lower levels of ritonavir during pregnancy compared to postpartum *[3]*.

Saquinavir (Invirase [Hard Gel Capsule], SQV) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Saquinavir was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Carcinogenicity studies found no indication of carcinogenic activity in rats and mice administered saquinavir for approximately 2 years, at plasma exposures approximately 60% of those obtained in humans at the recommended therapeutic dose (rats) and at exposures equivalent to those in humans at the recommended therapeutic dose (mice).
- Reproduction/fertility
  No effect of saquinavir has been seen on reproductive performance, fertility, or embryo survival in rats. Because of limited bioavailability of saquinavir in animals, the maximal plasma exposures achieved in rats were approximately 26% of those obtained in humans at the recommended clinical dose boosted with ritonavir.

- Teratogenicity/developmental toxicity
  No evidence of embryotoxicity or teratogenicity of saquinavir has been found in rabbits or rats. Because of limited bioavailability of saquinavir in animals and/or dosing limitations, the plasma exposures (AUC values) in the respective species were approximately 29% (using rat) and 21% (using rabbit) of those obtained in humans at the recommended clinical dose boosted with ritonavir.

- Placental and breast milk transfer
  Placental transfer of saquinavir in the rat and rabbit was minimal. In a Phase I study in pregnant women and their infants (PACTG 386, see below), transplacental passage of saquinavir was minimal *[1]*. Additionally, in a study of cord blood samples from eight women treated with saquinavir during pregnancy, the cord blood concentration of saquinavir was less than the assay limit of detection in samples from all women *[2]*. Saquinavir is excreted in the milk of lactating rats; it is not known if it is excreted in human milk.

- Human studies in pregnancy
  Three studies have evaluated the pharmacokinetics of saquinavir-hard gel capsules (HGC) combined with low-dose ritonavir (saquinavir-HGC 1,000 mg/ritonavir 100 mg given twice daily) in a total of 19 pregnant women; trough levels were greater than the target in all but 1 woman *[3,4]*. In a small study of 2 women who received saquinavir-HGC 1,200 mg/ritonavir 100 mg given once daily, trough levels were 285 and 684 ng/mL and the $AUC_{0\text{-}24}$ were 28,010 and 16,790 ng hour/mL, greater than the target AUC of 10,000 ng hour/mL *[5]*. Thus, the limited available data suggest that saquinavir-HGC 1,000 mg/ritonavir 100 mg given twice daily should achieve adequate trough levels in HIV-infected pregnant women. Data are too limited to recommend once-daily dosing at present. However, a recent analysis of saquinavir HGC administered once daily at 1,200mg/100mg ritonavir combined with various NRTIs during 46 pregnancies, demonstrated saquinavir levels greater than the target C_{min} in 46 (93.4%) of pregnancy episodes and undetectable viral load at delivery in 88% of episodes *[6]*. Target levels were achieved in the other 3 women with a dose of 1,600mg/100mg. The drug was well tolerated.

  The pharmacokinetics of the new 500-mg tablet formulation of saquinavir boosted with ritonavir in a dose of saquinavir 1,000 mg/ritonavir 100 mg given twice daily were studied in 14 HIV-infected pregnant women at 33 weeks gestation and parameters were comparable to those observed in nonpregnant individuals; none of the women had a subtherapeutic trough level *[7]*.

  One study of a saquinavir/ritonavir-based combination antiretroviral drug regimen in 42 women during pregnancy reported abnormal transaminase levels in 13 women (31%) within 2 to 4 weeks of treatment initiation, although the abnormalities were mild (toxicity grade 1–2 in most, grade 3 in 1 woman) *[8]*.

Tipranavir (Aptivus, TPV) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Tipranavir was neither mutagenic nor clastogenic in a battery of five *in vitro* and animal *in vivo* screening tests. Long-term carcinogenicity studies in mice and rats have been conducted with tipranavir. Mice were administered 30, 150, or 300 mg/kg/day tipranavir, 150/40 mg/kg/day tipranavir/ritonavir in combination, or 40 mg/kg/day ritonavir. The incidences of benign hepatocellular adenomas and combined adenomas/carcinomas were increased in females of all groups except in females given the low dose of tipranavir. These tumors were also increased in male mice at the high dose of tipranavir and in the tipranavir/ritonavir combination group. Hepatocellular carcinoma incidence was increased in female mice given the high dose of tipranavir and in both sexes receiving tipranavir/ritonavir. The combination of tipranavir and ritonavir caused an exposure-related increase in this same tumor type in both sexes. The clinical relevance of the carcinogenic findings in mice is unknown. Systemic exposures in mice (based on AUC or C_{max}) at all dose levels tested were below those in humans receiving the recommended dose level. Rats were administered 30, 100, or 300 mg/kg/day tipranavir, 100/26.7 mg/kg/day tipranavir/ritonavir in combination, or 10 mg/kg/day ritonavir. No drug-related findings in male rats were observed. At the highest dose of tipranavir, an increased incidence of benign follicular cell adenomas of the thyroid gland was observed in female rats. Based on AUC measurements, exposure to tipranavir at this dose level in rats is approximately equivalent to exposure in humans at the recommended therapeutic dose. This finding is probably not relevant to humans, because thyroid follicular cell adenomas are considered a rodent-specific effect secondary to enzyme induction.
- Reproduction/fertility
  Tipranavir had no effect on fertility or early embryonic development in rats at exposure levels similar to human exposures at the recommended clinical dose (500/200 mg per day of tipranavir/ritonavir).
- Teratogenicity/developmental toxicity
  No teratogenicity was detected in studies of pregnant rats and rabbits at exposure levels approximately 1.1-fold and 0.1-fold human exposure. In rats exposed to 400 mg/kg/day (~0.8-fold human exposure) and greater, fetal toxicity (decreased ossification and body weights) was observed. Fetal toxicity was not seen in rats and rabbits at levels of 0.2-fold and 0.1-fold exposures in humans. In rats, no adverse effects were seen on development at levels of 40 mg/kg/day (~0.2-fold human exposure), but growth inhibition in pups and maternal toxicity were seen at 400 mg/kg/day (~0.8-fold human exposure).
- Placental and breast milk transfer
  No animal studies of placental or breast milk passage of tipranavir have been reported. It is unknown if placental or breast milk passage of tipranavir occurs in humans.
- Human studies in pregnancy
  No studies of tipranavir have been conducted in pregnant women or neonates.

ENTRY INHIBITORS

Two drugs have been approved in this new class of antiretrovirals aimed at inhibiting viral binding or fusion of HIV to host target cells. Binding of the viral envelope glycoprotein gp120 to the CD4 receptor induces conformational changes that enable gp120 to interact with a chemokine receptor (e.g., CCR5 or CXCR4) on the host cell; binding of gp120 to the coreceptor causes subsequent conformational changes in the viral transmembrane glycoprotein gp41, exposing the "fusion peptide" of gp41, which inserts into the cell membrane. A helical region of gp41, called HR1, then interacts with a similar helical region, HR2, on gp41, resulting in a "zipping" together of the two helices and mediating the fusion of cellular and viral membranes. Enfuvirtide, which requires subcutaneous administration, is a synthetic 36 amino acid peptide derived from a naturally occurring motif within the HR2 domain of viral gp41, and the drug binds to the HR1 region, preventing the HR1-HR2 interaction and correct folding of gp41 into its secondary structure, thereby inhibiting virus-cell fusion. Enfuvirtide was approved for use in combination with other antiretroviral drugs to treat advanced HIV infection in adults and children aged 6 years or older. Maraviroc interferes with viral entry at the chemokine coreceptor level; it is a CCR5 coreceptor antagonist approved for combination therapy for HIV infection in adults infected with CCR5-tropic virus.

Enfuvirtide (Fuzeon, T-20) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Enfuvirtide was neither mutagenic or clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Long-term animal carcinogenicity studies of enfuvirtide have not been conducted.
- Reproduction/fertility animal studies
  Reproductive toxicity has been evaluated in rats and rabbits. Enfuvirtide produced no adverse effects on fertility of male or female rats at doses up 30 mg/kg/day administered subcutaneously (1.6 times the maximum recommended adult human daily dose on a m^2 basis).
- Teratogenicity/developmental toxicity animal studies
  Studies in rats and rabbits revealed no evidence of harm to the fetus from enfuvirtide administered in doses up to 27 times and 3.2 times, respectively, the adult human daily dose on a m^2 basis.
- Placental and breast milk passage
  Studies of radio-labeled enfuvirtide administered to lactating rats indicated radioactivity was present in the milk; however, it is not known if this reflected radio-labeled enfuvirtide or radio-labeled metabolites (e.g., amino acid and peptide fragments) of enfuvirtide. It is not known if enfuvirtide crosses the human placenta or is excreted in human milk. A published case report of two peripartum pregnant patients and their neonates and data from an *ex vivo* human placental cotyledon perfusion model suggest that enfuvirtide does not cross the placenta *[1,2]*.
- Human studies in pregnancy
  Very limited data exist on the use of enfuvirtide in pregnant women *[1,3,4]*; no data exist in neonates.

Maraviroc (Selzentry, MVC) is classified as FDA pregnancy category B.

- Animal carcinogenicity studies
  Maraviroc was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Long-term animal carcinogenicity studies found no increase in tumor incidence in mice (transgenic rasH2 mice) and rats at exposures up to 11-fold higher than experienced with human therapeutic exposure at the recommended clinical dose (300 mg twice daily).
- Reproduction/fertility animal studies
  Reproductive toxicity has been evaluated in rats. Maraviroc produced no adverse effects on fertility of male or female rats or sperm of male rats at exposures up to 20-fold higher than experienced with human therapeutic exposure at the recommended clinical dose (300 mg twice daily).
- Teratogenicity/developmental toxicity animal studies
  Studies in rats and rabbits revealed no evidence of harm to the fetus from maraviroc administered in doses up to 20-fold higher in rats and 5-fold higher in rabbits than experienced with human therapeutic exposure at the recommended clinical dose (300 mg twice daily).
- Placental and breast milk passage
  It is unknown if maraviroc crosses the placenta in animals or humans. Studies in lactating rats indicate that maraviroc is extensively secreted into rat milk.
- Human studies in pregnancy
  No studies of maraviroc have been conducted in pregnant women or neonates.
- Additional concerns
  Although no increase in malignancy has been observed, maraviroc has a potential for an increased risk of malignancy due to the drug's mechanism of action and possible effects on immune surveillance.

INTEGRASE INHIBITORS

One drug has been approved in this new class of antiretrovirals aimed at inhibiting the viral enzyme integrase, the viral enzyme catalyzing the two-step process of insertion of HIV DNA into the genome of the host cell. Integrase catalyzes a preparatory step that excises two nucleotides from one strand at both ends of the HIV DNA and a final "strand transfer" step that inserts the viral DNA into the exposed regions of cellular DNA. This second step of the integration process is targeted by the integrase inhibitor drug class. Integration is required for the stable maintenance of the viral genome as well as for efficient viral gene expression and replication. Integrase also affects retrotranscription and viral assembly. Host cells lack the integrase enzyme. Because HIV integrase represents a distinct therapeutic target, integrase inhibitors would be expected to maintain activity against HIV resistant to other classes of antiretroviral drugs.

Raltegravir (Isentress) is classified as FDA pregnancy category C.

- Animal carcinogenicity studies
  Raltegravir was neither mutagenic nor clastogenic in a series of *in vitro* and animal *in vivo* screening tests. Long-term animal carcinogenicity studies of raltegravir are ongoing.

- Reproduction/fertility animal studies
  Raltegravir produced no adverse effects on fertility of male or female rats at doses up to 600 mg/kg/day (providing exposures 3-fold higher than the exposure at the recommended adult human dose).
- Teratogenicity/developmental toxicity animal studies
  Studies in rats and rabbits revealed no evidence of treatment-related effects on embryonic/fetal survival or fetal weights from raltegravir administered in doses producing systemic exposures approximately 3- to 4-fold higher than the exposure at the recommended adult human daily dose. In rabbits, no treatment-related external, visceral, or skeletal changes were observed. However, treatment-related increases in the incidence of supernumerary ribs were seen in rats given raltegravir at 600 mg/kg/day (providing exposures 3-fold higher than the exposure at the recommended human daily dose).
- Placental and breast milk passage
  Placental transfer of raltegravir was demonstrated in both rats and rabbits. In rats given a maternal dose of 600 mg/kg/day, mean fetal blood concentrations were approximately 1.5- to 2.5-fold higher than in maternal plasma at 1 and 24 hours post-dose, respectively. However, in rabbits, the mean drug concentrations in fetal plasma were approximately 2% of the mean maternal plasma concentration at both 1 and 24 hours following a maternal dose of 1,000 mg/kg/day. Raltegravir is secreted in the milk of lactating rats, with mean drug concentrations in milk about 3-fold higher than in maternal plasma at a maternal dose of 600 mg/kg/day. There were no effects in rat offspring attributable to raltegravir exposure through breast milk.
- Human studies in pregnancy
  No studies of raltegravir have been conducted in pregnant women or neonates. It is unknown if raltegravir is secreted in human milk.

ANTIRETROVIRAL PREGNANCY REGISTRY

The Antiretroviral Pregnancy Registry is an epidemiologic project to collect observational, nonexperimental data on antiretroviral exposure during pregnancy for the purpose of assessing the potential teratogenicity of these drugs. Registry data will be used to supplement animal toxicology studies and assist clinicians in weighing the potential risks and benefits of treatment for individual patients. The registry is a collaborative project of the pharmaceutical manufacturers with an advisory committee of obstetric and pediatric practitioners.

It is strongly recommended that health care providers who are treating HIV-infected pregnant women and their newborns report cases of prenatal exposure to antiretroviral drugs (either alone or in combination) to the Antiretroviral Pregnancy Registry. The registry does not use patient names, and birth outcome follow-up is obtained by registry staff from the reporting physician.

UK National Guideline for the management of Pelvic Inflammatory Disease 2011

Clinical Effectiveness Group

British Association for Sexual Health and HIV

Guideline development group: Prof Jonathan Ross MB ChB MD FRCP (lead author) and Dr Gill McCarthy MB BS FRCP (lead editor on behalf of BASHH)

What is new in the 2011 guidelines?

- ceftriaxone has replaced cefoxitin to reflect the limited availability of cefoxitin in the UK and the equivalent efficacy of ceftriaxone
- use of ceftriaxone plus azithromycin as an alternative option for treating pelvic inflammatory disease
- moxifloxacin is an appropriate treatment for women with pelvic inflammatory disease at low risk of gonorrhoea where first line treatments have failed or cannot be tolerated
- greater clarity is provided on what issues should be discussed with women diagnosed with pelvic inflammatory disease
- the introduction of a patient information leaflet (appendix 1)

Introduction and methodology

Objectives

This guideline offers recommendations on the diagnostic tests, treatment regimens and health promotion principles needed for the effective management of pelvic inflammatory disease (PID) covering the management of the initial presentation, as well as how to reduce transmission and future infection.

It is aimed primarily at women aged 16 years or older (see specific guidelines for those under 16) presenting to health care professionals working in departments offering level 3 care in STI management within the United Kingdom. However, the principles of the recommendations should be adopted across all levels - level 1 and 2 providers may need to develop local care pathways where appropriate.

Included in the guideline is a patient information leaflet (appendix 1)

Search strategy

Five reference sources were used to provide a comprehensive basis for the guideline:

1. **Medline and Embase Search**

a.1987 – January 2010

The search strategy comprised the following terms in the title or abstract: 'pelvic inflammatory disease', 'adnexitis', 'oophoritis', 'parametritis', 'salpingitis', 'endometritis', 'PID' (excluding 'primary immune deficiency'), 'adnexal disease' or 'adnexal disease'. 10422 citations were identified.

b.1963 - 1986

The search strategy comprised the following terms in the title or abstract: 'pelvic inflammatory disease', 'adnexitis', 'oophoritis', 'parametritis', 'salpingitis' or 'adnexal disease'. The dataset was then limited to AIM journals and human subjects, identifying 2321 citations.

2. **2010 CDC STD Treatment Guidelines (www.cdc.gov/std/)**

3. **2009 RCOG Green Top Guidelines – Management of Acute Pelvic Inflammatory Disease (www.rcog.org.uk)**

4. **Royal College of Obstetrics and Gynaecology Working Group on PID Report 1996**[1]

5. **Cochrane Collaboration Databases (www.cochrane.org)**

Methods

Article titles and abstracts were reviewed and if relevant the full text article obtained. Priority was given to randomised controlled trial and systematic review evidence, and recommendations made and graded on the basis of best available evidence.

Piloting and feedback

The initial draft of the guideline including the patient information leaflet was piloted for validation by the Clinical Effectiveness Group (CEG) of BASHH using a sample of UK genitourinary medicine clinics. A standardised feed back form was completed by each pilot site and the guideline amended by the CEG editor. The final guideline was then reviewed by the CEG using the AGREE instrument before posting it on the BASHH website for external peer review for a 3 month period. Comments received were collated by the CEG editor and sent to the guideline chair for review and action. The final guideline was approved by the CEG and a review date agreed before publication on the BASHH website.

Aetiology

- PID is usually the result of infection ascending from the endocervix causing endometritis, salpingitis, parametritis, oophoritis, tuboovarian abcess and/or pelvic peritonitis.
- *Neisseria gonorrhoeae* and *Chlamydia trachomatis* have been identified as causative agents [1, 2] but account for only a quarter of cases in the UK, whilst *Gardnerella vaginalis*, anaerobes (including *Prevotella*, *Atopobium* and *Leptotrichia*) and other organisms commonly found in the vagina may also be implicated. *Mycoplasma genitalium* has also been associated with upper genital tract infection in women[3].

Clinical Features

Symptoms

The following features are suggestive of a diagnosis of PID[1, 2, 4, 5]:

- lower abdominal pain which is typically bilateral
- deep dyspareunia
- abnormal vaginal bleeding, including post coital, inter-menstrual bleeding and menorrhagia
- abnormal vaginal or cervical discharge which is often purulent

Signs

- lower abdominal tenderness which is usually bilateral
- adnexal tenderness on bimanual vaginal examination
- cervical motion tenderness on bimanual vaginal examination
- fever (>38°C)

A diagnosis of PID, and empirical antibiotic treatment, should be considered and usually offered in any young (under 25) sexually active woman who has recent onset, bilateral lower abdominal pain associated with local tenderness on bimanual vaginal examination, in whom pregnancy has been excluded.

Complications

- Women with HIV may have more severe symptoms associated with PID but respond well to standard antibiotic therapy[6]. No change in treatment recommendations compared to HIV uninfected patients is required[7-9]. (Grade B [III])
- The Fitz-Hugh-Curtis syndrome comprises right upper quadrant pain associated with perihepatitis which occurs in some women with PID. Although laparoscopic division of hepatic adhesions has been performed, there is insufficient clinical trial evidence to make specific recommendations for treatment beyond those for uncomplicated PID.
- The randomised controlled trial evidence for whether an intrauterine contraceptive device should be left in situ or removed in women presenting with PID is limited[10, 11]. Removal of the IUD should be considered and may be associated with better short term clinical outcomes[10]. The decision to remove the IUD needs to be balanced against the risk of pregnancy in those who have had otherwise unprotected intercourse in the preceding 7 days. Hormonal emergency contraception may be appropriate for some women in this situation.

Diagnosis

- PID may be symptomatic or asymptomatic. Even when present, clinical symptoms and signs lack sensitivity and specificity (the positive predictive value of a clinical diagnosis is 65-90% compared to laparoscopic diagnosis[2, 4, 5])
- Testing for gonorrhoea and Chlamydia in the lower genital tract is recommended since a positive result supports the diagnosis of PID. The absence of infection at this site does not exclude PID however[2, 4, 5]
- An elevated ESR or C reactive protein also supports the diagnosis but is non-specific [12].
- The **absence** of endocervical or vaginal pus cells has a good negative predictive value (95%) for a diagnosis of PID but their **presence** is non-specific (poor positive predictive value – 17%)[13].

The differential diagnosis of lower abdominal pain in a young woman includes:

- ectopic pregnancy – pregnancy should be excluded in all women suspected of having PID

- acute appendicitis – nausea and vomiting occurs in most patients with appendicitis but only 50% of those with PID. Cervical movement pain will occur in about a quarter of women with appendicitis [14, 15].
- endometriosis – the relationship between symptoms and the menstrual cycle may be helpful in establishing a diagnosis
- complications of an ovarian cyst e.g. torsion or rupture – often of sudden onset
- urinary tract infection – often associated with dysuria and/or urinary frequency
- functional pain – may be associated with longstanding symptoms

Management

It is likely that delaying treatment increases the risk of long term sequelae such as ectopic pregnancy, infertility and pelvic pain[16]. Because of this, and the lack of definitive diagnostic criteria, a low threshold for empiric treatment of PID is recommended. Broad spectrum antibiotic therapy is required to cover *N. gonorrhoeae*, *C. trachomatis* and a variety of aerobic and anaerobic bacteria commonly isolated from the upper genital tract in women with PID[1, 2].

Some of the best evidence for the effectiveness of antibiotic treatment in preventing the long term complications of PID comes from the PEACH study where women were treated with cefoxitin followed by doxycycline – pregnancy rates after 3 years were similar or higher than those in the general population [17, 18].

The choice of an appropriate treatment regimen may be influenced by:

- robust evidence on local antimicrobial sensitivity patterns
- robust evidence on the local epidemiology of specific infections in this setting
- cost
- patient preference and compliance
- severity of disease

General Advice

Rest is advised for those with severe disease. (Grade C [IV])

Appropriate analgesia should be provided. (Grade C [IV])

Intravenous therapy is recommended for patients with more severe clinical disease (Grade C [IV]) e.g. pyrexia > 38^{o}C, clinical signs of tubo-ovarian abcess, signs of pelvic peritonitis.

Patients should be advised to avoid unprotected intercourse until they, and their partner(s), have completed treatment and follow-up (Grade C [IV]).

- A detailed explanation of their condition with particular emphasis on the long term implications for the health of themselves and their partner(s) should be provided, reinforced with clear and accurate written information (Grade C [IV]). A patient information leaflet is included in appendix 1 of this guideline.

When giving information to patients, the clinician should consider the following:

- an explanation of what treatment is being given and its possible adverse effects
- that following treatment fertility is usually maintained but there remains a risk of future infertility, chronic pelvic pain or ectopic pregnancy
- clinically more severe disease is associated with a greater risk of sequelae
- repeat episodes of PID are associated with an exponential increase in the risk of infertility
- the earlier treatment is given the lower the risk of future fertility problems.
- future use of barrier contraception will significantly reduce the risk of PID
- the need to screen her sexual contacts for infection to prevent her becoming reinfected

Outpatient therapy is as effective as inpatient treatment for patients with clinically mild to moderate PID[17]. Admission for parenteral therapy, observation, further investigation and/or possible surgical intervention should be considered in the following situations[19]:

- a surgical emergency cannot be excluded
- lack of response to oral therapy
- clinically severe disease
- presence of a tuboovarian abcess
- intolerance to oral therapy
- pregnancy

Further Investigation

All sexually active patients should be offered:

- a pregnancy test
- screening for sexually transmitted infections including HIV[20]

Treatment

The following antibiotic regimens are evidence based.

Recommended Regimens

All the recommended regimens are of similar efficacy.

Outpatient Regimens

i.m. ceftriaxone* 250mg single dose followed by oral doxycycline 100mg twice daily *plus* metronidazole 400mg twice daily for 14 days

Grade A (Ib) [21-23]

*Clinical trial data support the use of cefoxitin for the treatment of PID but this agent is not easily available in the UK so ceftriaxone, which has a similar spectrum of activity, is recommended.

oral ofloxacin 400mg twice daily *plus* oral metronidazole 400mg twice daily for 14 days

Grade A (Ib) [23-27]

Metronidazole is included in some regimens to improve coverage for anaerobic bacteria. Anaerobes are of relatively greater importance in patients with severe PID and metronidazole may be discontinued in those patients with mild or moderate PID who are unable to tolerate it.

Ofloxacin and moxifloxacin should be avoided in patients who are at high risk of gonococcal PID because of increasing quinolone resistance in the UK (e.g. when the patient's partner has gonorrhoea, in clinically severe disease, following sexual contact abroad). Quinolones should also be avoided as first line empirical treatment for PID in areas where >5% of PID is caused by quinolone resistant *Neisseria gonorrhoeae*.

Levofloxacin is the L isomer of ofloxacin[28] and has the advantage of once daily dosing (500mg OD for 14 days). It may be used as a more convenient alternative to ofloxacin.[29]

Replacing intramuscular ceftriaxone with an oral cephalosporin (e.g. cefixime) is not recommended because there is no clinical trial evidence to support its use, and tissue levels are likely to be lower which might impact on efficacy. Reports of decreasing susceptibility of *Neisseria gonorrhoeae* to cephalosporins also supports the use of parenteral based regimens when gonococcal PID is suspected (to maximise tissue levels and overcome low level resistance).

Alternative Regimens

intramuscular ceftriaxone 250 mg immediately, followed by azithromycin 1 g/week for 2 weeks

Grade A (Ib)[30, 31]

Clinical trial evidence for this regimen is limited but it may be used when the treatments above are not appropriate e.g. allergy, intolerance:

oral moxifloxacin 400mg once daily for 14 days

Grade A (Ib)[29, 32, 33]

Three large RCTs support the efficacy of moxifloxacin for PID but because of evidence of an increased risk of liver reactions and other serious risks (such as QT interval prolongation), oral moxifloxacin should be used only when it is considered inappropriate to use the other antibacterial agents recommended for PID or when these have failed.

Inpatient Regimens

Intravenous therapy should be continued until 24 hours after clinical improvement and then switched to oral. Intravenous doxycycline is not currently licensed in the UK but is available from IDIS world medicines (01932 824100).

i.v. ceftriaxone 2g daily *plus* i.v. doxycycline 100mg twice daily (oral doxycycline may be used if tolerated) followed by oral doxycycline 100mg twice daily *plus* oral metronidazole 400mg twice daily for a total of 14 days

Grade A (Ib) [22, 23]

i.v. clindamycin 900mg 3 times daily *plus* i.v. gentamicin (2mg/kg loading dose) followed by 1.5mg/kg 3 times daily [a single daily dose of 7mg/kg may be substituted]) followed by either oral clindamycin 450mg 4 times daily or oral doxycycline 100mg twice daily plus oral metronidazole 400mg twice daily to complete 14 days

Grade A (Ib) [22]

Gentamicin levels need to be monitored if this regimen is used.

Alternative Regimens

Clinical trial evidence for the following regimens is more limited but they may be used when the treatments above are not appropriate e.g. allergy, intolerance:

i.v. ofloxacin 400mg BD *plus* i.v. metronidazole 500mg TID for 14 days

Grade B (III) [23-25, 34]

i.v. ciprofloxacin 200mg BD plus i.v. (or oral) doxycycline 100mg BD plus i.v. metronidazole 500mg TID for 14 days

Grade B (III) [24, 35]

Allergy

There is no clear evidence of the superiority of any one of the suggested regimens over the others. Therefore patients known to be allergic to one of the suggested regimens should be treated with an alternative.

Pregnancy and Breastfeeding

- PID in pregnancy is associated with an increase in both maternal and fetal morbidity, therefore parenteral therapy is advised although none of the suggested evidence based regimens are of proven safety in this situation.
- There are insufficient data from clinical trials to recommend a specific regimen and empirical therapy with agents effective against gonorrhoea, chlamydia and anaerobic infections should be considered taking into account local antibiotic sensitivity patterns (e.g. i.m. ceftriaxone plus oral or i.v. erythromycin, with the possible addition of oral or i.v. metronidazole 500mg 3 times daily in clinically severe disease) (Grade C [IV]).
- The risk of giving any of the recommended antibiotic regimens (listed above for non pregnant women) in very early pregnancy (prior to a pregnancy test becoming positive) is justified by the need to provide effective therapy and the low risk to the foetus (personal communication, UK National Teratology Information Service – 11.2.10).

Surgical Management

- Laparoscopy may help early resolution of the disease by dividing adhesions and draining pelvic abscesses[36] but ultrasound guided aspiration of pelvic fluid collections is less invasive and may be equally effective.[37, 38]
- It is also possible to perform adhesiolysis in cases of perihepatitis although there is no evidence whether this is superior to using only antibiotic therapy

Sexual Partners

- Current male partners of women with PID should be contacted and offered health advice and screening for gonorrhoea and chlamydia. Other recent sexual partners may also be offered screening - tracing of contacts within a 6 month period of onset of symptoms is recommended but this time period may be influenced by the sexual history (Grade C [IV]).
- Gonorrhoea or chlamydia diagnosed in the male partner should be treated appropriately and concurrently with the index patient. (Grade C [IV]).
- Because many cases of PID are not associated with gonorrhoea or chlamydia, broad spectrum empirical therapy should also be offered to male partners e.g. azithromycin 1g single dose (Grade C [IV]).
- If screening for gonorrhoea is not available additional specific antibiotics effective against *Neisseria gonorrhoeae* should be offered e.g. i.m. ceftriaxone 250mg single dose (see also UK National Guidelines for Gonorrhoea) (Grade C [IV]).
- Partners should be advised to avoid intercourse until they and the index patient have completed the treatment course (Grade C [IV]).

Follow Up

Review at 72 hours is recommended [5], particularly for those with a moderate or severe clinical presentation, and should show a substantial improvement in clinical symptoms and signs (Grade C [IV]). Failure to do so suggests the need for further investigation, parenteral therapy and/or surgical intervention.

Further review 2-4 weeks (Grade C [IV]) after therapy may be useful to ensure:

- adequate clinical response to treatment
- compliance with oral antibiotics
- screening and treatment of sexual contacts
- awareness of the significance of PID and its sequelae
- repeat pregnancy test, if clinically indicated

Repeat testing for gonorrhoea or chlamydia after 2 to 4 weeks is appropriate in those in whom persisting symptoms, antibiotic resistance pattern (gonorrhoea only), compliance with antibiotics and/or tracing of sexual contacts indicate the possibility of persisting or recurrent infection.

Auditable Outcome Measures

Appropriate short term audit outcomes include:

- proportion of women receiving treatment with a recommended regimen – target 95%
- number of named male contacts screened for infection and/or treated – target 0.4 (large urban centres) or 0.6 (other centres) per index case[39]

Qualifying statement

The recommendations in this guideline may not be appropriate for use in all clinical situations. Decisions to follow these recommendations must be based on the professional judgement of the clinician and consideration of individual patient circumstances and available resources.

All possible care has been undertaken to ensure the publication of the correct dosage of medication and route of administration. However, it remains the responsibility of the prescribing physician to ensure the accuracy and appropriateness of the medication they prescribe.

Editorial independence

This guideline was commissioned, edited and endorsed by the BASHH CEG without external funding being sought or obtained.

Declarations of interest

All members of the guideline writing committee completed the BASHH conflict of interest declaration detailed below at the time the guideline's final draft was submitted to the CEG. JR has received consultancy fees from Bayer pharma.

Currently in preparation – see BASHH website in due course for downloadable document.

UK National Guideline for the management of Pelvic Inflammatory Disease 2011

Clinical Effectiveness Group

British Association for Sexual Health and HIV

Guideline development group: Prof Jonathan Ross MB ChB MD FRCP (lead author) and Dr Gill McCarthy MB BS FRCP (lead editor on behalf of BASHH)

What is new in the 2011 guidelines?

- ceftriaxone has replaced cefoxitin to reflect the limited availability of cefoxitin in the UK and the equivalent efficacy of ceftriaxone
- use of ceftriaxone plus azithromycin as an alternative option for treating pelvic inflammatory disease
- moxifloxacin is an appropriate treatment for women with pelvic inflammatory disease at low risk of gonorrhoea where first line treatments have failed or cannot be tolerated
- greater clarity is provided on what issues should be discussed with women diagnosed with pelvic inflammatory disease
- the introduction of a patient information leaflet (appendix 1)

Introduction and methodology

Objectives

This guideline offers recommendations on the diagnostic tests, treatment regimens and health promotion principles needed for the effective management of pelvic inflammatory disease (PID) covering the management of the initial presentation, as well as how to reduce transmission and future infection.

It is aimed primarily at women aged 16 years or older (see specific guidelines for those under 16) presenting to health care professionals working in departments offering level 3 care in STI management within the United Kingdom. However, the principles of the recommendations should be adopted across all levels - level 1 and 2 providers may need to develop local care pathways where appropriate.

Included in the guideline is a patient information leaflet (appendix 1)

Search strategy

Five reference sources were used to provide a comprehensive basis for the guideline:

1. **Medline and Embase Search**

a.1987 – January 2010

The search strategy comprised the following terms in the title or abstract: 'pelvic inflammatory disease', 'adnexitis', 'oophoritis', 'parametritis', 'salpingitis', 'endometritis', 'PID' (excluding 'primary immune deficiency'), 'adnexal disease' or 'adnexal disease'. 10422 citations were identified.

b.1963 - 1986

The search strategy comprised the following terms in the title or abstract: 'pelvic inflammatory disease', 'adnexitis', 'oophoritis', 'parametritis', 'salpingitis' or 'adnexal disease'. The dataset was then limited to AIM journals and human subjects, identifying 2321 citations.

2. **2010 CDC STD Treatment Guidelines (www.cdc.gov/std/)**

3. **2009 RCOG Green Top Guidelines – Management of Acute Pelvic Inflammatory Disease (www.rcog.org.uk)**

4. **Royal College of Obstetrics and Gynaecology Working Group on PID Report 1996**[1]

5. **Cochrane Collaboration Databases (www.cochrane.org)**

Methods

Article titles and abstracts were reviewed and if relevant the full text article obtained. Priority was given to randomised controlled trial and systematic review evidence, and recommendations made and graded on the basis of best available evidence.

Piloting and feedback

The initial draft of the guideline including the patient information leaflet was piloted for validation by the Clinical Effectiveness Group (CEG) of BASHH using a sample of UK genitourinary medicine clinics. A standardised feed back form was completed by each pilot site and the guideline amended by the CEG editor. The final guideline was then reviewed by the CEG using the AGREE instrument before posting it on the BASHH website for external peer review for a 3 month period. Comments received were collated by the CEG editor and sent to the guideline chair for review and action. The final guideline was approved by the CEG and a review date agreed before publication on the BASHH website.

Aetiology

- PID is usually the result of infection ascending from the endocervix causing endometritis, salpingitis, parametritis, oophoritis, tuboovarian abcess and/or pelvic peritonitis.
- *Neisseria gonorrhoeae* and *Chlamydia trachomatis* have been identified as causative agents [1, 2] but account for only a quarter of cases in the UK, whilst *Gardnerella vaginalis*, anaerobes (including *Prevotella*, *Atopobium* and *Leptotrichia*) and other organisms commonly found in the vagina may also be implicated. *Mycoplasma genitalium* has also been associated with upper genital tract infection in women[3].

Clinical Features

Symptoms

The following features are suggestive of a diagnosis of PID[1, 2, 4, 5]:

- lower abdominal pain which is typically bilateral
- deep dyspareunia
- abnormal vaginal bleeding, including post coital, inter-menstrual bleeding and menorrhagia
- abnormal vaginal or cervical discharge which is often purulent

Signs

- lower abdominal tenderness which is usually bilateral
- adnexal tenderness on bimanual vaginal examination
- cervical motion tenderness on bimanual vaginal examination
- fever (>38°C)

A diagnosis of PID, and empirical antibiotic treatment, should be considered and usually offered in any young (under 25) sexually active woman who has recent onset, bilateral lower abdominal pain associated with local tenderness on bimanual vaginal examination, in whom pregnancy has been excluded.

Complications

- Women with HIV may have more severe symptoms associated with PID but respond well to standard antibiotic therapy[6]. No change in treatment recommendations compared to HIV uninfected patients is required[7-9]. (Grade B [III])
- The Fitz-Hugh-Curtis syndrome comprises right upper quadrant pain associated with perihepatitis which occurs in some women with PID. Although laparoscopic division of hepatic adhesions has been performed, there is insufficient clinical trial evidence to make specific recommendations for treatment beyond those for uncomplicated PID.
- The randomised controlled trial evidence for whether an intrauterine contraceptive device should be left in situ or removed in women presenting with PID is limited[10, 11]. Removal of the IUD should be considered and may be associated with better short term clinical outcomes[10]. The decision to remove the IUD needs to be balanced against the risk of pregnancy in those who have had otherwise unprotected intercourse in the preceding 7 days. Hormonal emergency contraception may be appropriate for some women in this situation.

Diagnosis

- PID may be symptomatic or asymptomatic. Even when present, clinical symptoms and signs lack sensitivity and specificity (the positive predictive value of a clinical diagnosis is 65-90% compared to laparoscopic diagnosis[2, 4, 5])
- Testing for gonorrhoea and Chlamydia in the lower genital tract is recommended since a positive result supports the diagnosis of PID. The absence of infection at this site does not exclude PID however[2, 4, 5]
- An elevated ESR or C reactive protein also supports the diagnosis but is non-specific [12].
- The **absence** of endocervical or vaginal pus cells has a good negative predictive value (95%) for a diagnosis of PID but their **presence** is non-specific (poor positive predictive value – 17%)[13].

The differential diagnosis of lower abdominal pain in a young woman includes:

- ectopic pregnancy – pregnancy should be excluded in all women suspected of having PID

- acute appendicitis – nausea and vomiting occurs in most patients with appendicitis but only 50% of those with PID. Cervical movement pain will occur in about a quarter of women with appendicitis [14, 15].
- endometriosis – the relationship between symptoms and the menstrual cycle may be helpful in establishing a diagnosis
- complications of an ovarian cyst e.g. torsion or rupture – often of sudden onset
- urinary tract infection – often associated with dysuria and/or urinary frequency
- functional pain – may be associated with longstanding symptoms

Management

It is likely that delaying treatment increases the risk of long term sequelae such as ectopic pregnancy, infertility and pelvic pain[16]. Because of this, and the lack of definitive diagnostic criteria, a low threshold for empiric treatment of PID is recommended. Broad spectrum antibiotic therapy is required to cover *N. gonorrhoeae*, *C. trachomatis* and a variety of aerobic and anaerobic bacteria commonly isolated from the upper genital tract in women with PID[1, 2].

Some of the best evidence for the effectiveness of antibiotic treatment in preventing the long term complications of PID comes from the PEACH study where women were treated with cefoxitin followed by doxycycline – pregnancy rates after 3 years were similar or higher than those in the general population [17, 18].

The choice of an appropriate treatment regimen may be influenced by:

- robust evidence on local antimicrobial sensitivity patterns
- robust evidence on the local epidemiology of specific infections in this setting
- cost
- patient preference and compliance
- severity of disease

General Advice

Rest is advised for those with severe disease. (Grade C [IV])

Appropriate analgesia should be provided. (Grade C [IV])

Intravenous therapy is recommended for patients with more severe clinical disease (Grade C [IV]) e.g. pyrexia > 38^{o}C, clinical signs of tubo-ovarian abcess, signs of pelvic peritonitis.

Patients should be advised to avoid unprotected intercourse until they, and their partner(s), have completed treatment and follow-up (Grade C [IV]).

- A detailed explanation of their condition with particular emphasis on the long term implications for the health of themselves and their partner(s) should be provided, reinforced with clear and accurate written information (Grade C [IV]). A patient information leaflet is included in appendix 1 of this guideline.

When giving information to patients, the clinician should consider the following:

- an explanation of what treatment is being given and its possible adverse effects
- that following treatment fertility is usually maintained but there remains a risk of future infertility, chronic pelvic pain or ectopic pregnancy
- clinically more severe disease is associated with a greater risk of sequelae
- repeat episodes of PID are associated with an exponential increase in the risk of infertility
- the earlier treatment is given the lower the risk of future fertility problems.
- future use of barrier contraception will significantly reduce the risk of PID
- the need to screen her sexual contacts for infection to prevent her becoming reinfected

Outpatient therapy is as effective as inpatient treatment for patients with clinically mild to moderate PID[17]. Admission for parenteral therapy, observation, further investigation and/or possible surgical intervention should be considered in the following situations[19]:

- a surgical emergency cannot be excluded
- lack of response to oral therapy
- clinically severe disease
- presence of a tuboovarian abcess
- intolerance to oral therapy
- pregnancy

Further Investigation

All sexually active patients should be offered:

- a pregnancy test
- screening for sexually transmitted infections including HIV[20]

Treatment

The following antibiotic regimens are evidence based.

Recommended Regimens

All the recommended regimens are of similar efficacy.

Outpatient Regimens

i.m. ceftriaxone* 250mg single dose followed by oral doxycycline 100mg twice daily *plus* metronidazole 400mg twice daily for 14 days

Grade A (Ib) [21-23]

*Clinical trial data support the use of cefoxitin for the treatment of PID but this agent is not easily available in the UK so ceftriaxone, which has a similar spectrum of activity, is recommended.

oral ofloxacin 400mg twice daily *plus* oral metronidazole 400mg twice daily for 14 days

Grade A (Ib) [23-27]

Metronidazole is included in some regimens to improve coverage for anaerobic bacteria. Anaerobes are of relatively greater importance in patients with severe PID and metronidazole may be discontinued in those patients with mild or moderate PID who are unable to tolerate it.

Ofloxacin and moxifloxacin should be avoided in patients who are at high risk of gonococcal PID because of increasing quinolone resistance in the UK (e.g. when the patient's partner has gonorrhoea, in clinically severe disease, following sexual contact abroad). Quinolones should also be avoided as first line empirical treatment for PID in areas where >5% of PID is caused by quinolone resistant *Neisseria gonorrhoeae*.

Levofloxacin is the L isomer of ofloxacin[28] and has the advantage of once daily dosing (500mg OD for 14 days). It may be used as a more convenient alternative to ofloxacin.[29]

Replacing intramuscular ceftriaxone with an oral cephalosporin (e.g. cefixime) is not recommended because there is no clinical trial evidence to support its use, and tissue levels are likely to be lower which might impact on efficacy. Reports of decreasing susceptibility of *Neisseria gonorrhoeae* to cephalosporins also supports the use of parenteral based regimens when gonococcal PID is suspected (to maximise tissue levels and overcome low level resistance).

Alternative Regimens

intramuscular ceftriaxone 250 mg immediately, followed by azithromycin 1 g/week for 2 weeks

Grade A (Ib)[30, 31]

Clinical trial evidence for this regimen is limited but it may be used when the treatments above are not appropriate e.g. allergy, intolerance:

oral moxifloxacin 400mg once daily for 14 days

Grade A (Ib)[29, 32, 33]

Three large RCTs support the efficacy of moxifloxacin for PID but because of evidence of an increased risk of liver reactions and other serious risks (such as QT interval prolongation), oral moxifloxacin should be used only when it is considered inappropriate to use the other antibacterial agents recommended for PID or when these have failed.

Inpatient Regimens

Intravenous therapy should be continued until 24 hours after clinical improvement and then switched to oral. Intravenous doxycycline is not currently licensed in the UK but is available from IDIS world medicines (01932 824100).

i.v. ceftriaxone 2g daily *plus* i.v. doxycycline 100mg twice daily (oral doxycycline may be used if tolerated) followed by oral doxycycline 100mg twice daily *plus* oral metronidazole 400mg twice daily for a total of 14 days

Grade A (Ib) [22, 23]

i.v. clindamycin 900mg 3 times daily *plus* i.v. gentamicin (2mg/kg loading dose) followed by 1.5mg/kg 3 times daily [a single daily dose of 7mg/kg may be substituted]) followed by either oral clindamycin 450mg 4 times daily or oral doxycycline 100mg twice daily plus oral metronidazole 400mg twice daily to complete 14 days

Grade A (Ib) [22]

Gentamicin levels need to be monitored if this regimen is used.

Alternative Regimens

Clinical trial evidence for the following regimens is more limited but they may be used when the treatments above are not appropriate e.g. allergy, intolerance:

i.v. ofloxacin 400mg BD *plus* i.v. metronidazole 500mg TID for 14 days

Grade B (III) [23-25, 34]

i.v. ciprofloxacin 200mg BD plus i.v. (or oral) doxycycline 100mg BD plus i.v. metronidazole 500mg TID for 14 days

Grade B (III) [24, 35]

Allergy

There is no clear evidence of the superiority of any one of the suggested regimens over the others. Therefore patients known to be allergic to one of the suggested regimens should be treated with an alternative.

Pregnancy and Breastfeeding

- PID in pregnancy is associated with an increase in both maternal and fetal morbidity, therefore parenteral therapy is advised although none of the suggested evidence based regimens are of proven safety in this situation.
- There are insufficient data from clinical trials to recommend a specific regimen and empirical therapy with agents effective against gonorrhoea, chlamydia and anaerobic infections should be considered taking into account local antibiotic sensitivity patterns (e.g. i.m. ceftriaxone plus oral or i.v. erythromycin, with the possible addition of oral or i.v. metronidazole 500mg 3 times daily in clinically severe disease) (Grade C [IV]).
- The risk of giving any of the recommended antibiotic regimens (listed above for non pregnant women) in very early pregnancy (prior to a pregnancy test becoming positive) is justified by the need to provide effective therapy and the low risk to the foetus (personal communication, UK National Teratology Information Service – 11.2.10).

Surgical Management

- Laparoscopy may help early resolution of the disease by dividing adhesions and draining pelvic abscesses[36] but ultrasound guided aspiration of pelvic fluid collections is less invasive and may be equally effective.[37, 38]
- It is also possible to perform adhesiolysis in cases of perihepatitis although there is no evidence whether this is superior to using only antibiotic therapy

Sexual Partners

- Current male partners of women with PID should be contacted and offered health advice and screening for gonorrhoea and chlamydia. Other recent sexual partners may also be offered screening - tracing of contacts within a 6 month period of onset of symptoms is recommended but this time period may be influenced by the sexual history (Grade C [IV]).
- Gonorrhoea or chlamydia diagnosed in the male partner should be treated appropriately and concurrently with the index patient. (Grade C [IV]).
- Because many cases of PID are not associated with gonorrhoea or chlamydia, broad spectrum empirical therapy should also be offered to male partners e.g. azithromycin 1g single dose (Grade C [IV]).
- If screening for gonorrhoea is not available additional specific antibiotics effective against *Neisseria gonorrhoeae* should be offered e.g. i.m. ceftriaxone 250mg single dose (see also UK National Guidelines for Gonorrhoea) (Grade C [IV]).
- Partners should be advised to avoid intercourse until they and the index patient have completed the treatment course (Grade C [IV]).

Follow Up

Review at 72 hours is recommended [5], particularly for those with a moderate or severe clinical presentation, and should show a substantial improvement in clinical symptoms and signs (Grade C [IV]). Failure to do so suggests the need for further investigation, parenteral therapy and/or surgical intervention.

Further review 2-4 weeks (Grade C [IV]) after therapy may be useful to ensure:

- adequate clinical response to treatment
- compliance with oral antibiotics
- screening and treatment of sexual contacts
- awareness of the significance of PID and its sequelae
- repeat pregnancy test, if clinically indicated

Repeat testing for gonorrhoea or chlamydia after 2 to 4 weeks is appropriate in those in whom persisting symptoms, antibiotic resistance pattern (gonorrhoea only), compliance with antibiotics and/or tracing of sexual contacts indicate the possibility of persisting or recurrent infection.

Auditable Outcome Measures

Appropriate short term audit outcomes include:

- proportion of women receiving treatment with a recommended regimen – target 95%
- number of named male contacts screened for infection and/or treated – target 0.4 (large urban centres) or 0.6 (other centres) per index case[39]

Qualifying statement

The recommendations in this guideline may not be appropriate for use in all clinical situations. Decisions to follow these recommendations must be based on the professional judgement of the clinician and consideration of individual patient circumstances and available resources.

All possible care has been undertaken to ensure the publication of the correct dosage of medication and route of administration. However, it remains the responsibility of the prescribing physician to ensure the accuracy and appropriateness of the medication they prescribe.

Editorial independence

This guideline was commissioned, edited and endorsed by the BASHH CEG without external funding being sought or obtained.

Declarations of interest

All members of the guideline writing committee completed the BASHH conflict of interest declaration detailed below at the time the guideline's final draft was submitted to the CEG. JR has received consultancy fees from Bayer pharma.

United Kingdom National Guideline on the Management of Vulvovaginal Candidiasis (2007)

Clinical Effectiveness Group
British Association of Sexual Health and HIV

Introduction and Methodology

Scope and Purpose

The main objective is to assist practitioners in the management of uncomplicated and complicated Vulvovaginal Candidiasis.

This guideline offers recommendations on the diagnostic tests, treatment regimens and health promotion principles needed for the effective management of Vulvovaginal Candidiasis.

It is aimed primarily at people aged 16 years or older (see specific guidelines for those under 16) presenting to health care professionals, working in departments offering level 3 care in STI management (see national strategy[(2)]) within the United Kingdom. However, the principles of the recommendations should be adopted across all levels (levels 1 and 2 may need to develop, where appropriate, local care pathways).

Stakeholder Involvement

This guideline has been produced by physicians, including those with a specialist interest, with input from patients attending UK GUM clinics.
The draft guideline was placed on the BASHH website for a three month consultation period.
The process was overseen by the BASHH Clinical Effectiveness Group (CEG).
This is the second revision of the guideline first published in 1999.

Rigour of Development

An extensive literature review was performed using Medline for the years 1966-2007. MEDLINE search-keywords: vulvovaginal candidiasis, vaginal candidosis, vaginal candida. The resulting articles were handsearched and sorted. Further references were obtained from these articles.

The Cochrane Library was searched; search-keywords were vulvovaginal candidiasis, vaginal candidosis, vaginal candida (2007).

Aetiology

Causative Agents

Candida albicans 80-92%[1;2]
Non-*albicans* species e.g. *C. glabrata*, *C. tropicalis*, *C. krusei*, *C. parapsilosis*, and *Saccharomyces cerevisiae*

Clinical Features

Symptoms

Vulval itch
Vulval soreness
Vaginal discharge
Superficial dyspareunia
External dysuria

Signs

Erythema
Fissuring
Discharge, typically curdy but may be thin. Non-offensive
Oedema
Satellite lesions
Excoriation

None of these symptoms or signs are pathognomonic for vulvovaginal candidiasis; corroborative evidence of laboratory tests should be sought[3] as many women (more than half of self-diagnosed women in one study[4]) may have other conditions e.g. dermatitis, allergic reactions, lichen sclerosus. In addition, symptoms/signs are no guide to species.[3;5]

10-20% of women during reproductive years may be colonized with *Candida sp*.[6;7] but have no clinical signs or symptoms. These women do not require treatment.

Vulvo-vaginal candidiasis is mostly uncomplicated unless the following are present when it is regarded as complicated:

- Severe symptoms (a subjective assessment)

- Pregnancy
- Recurrent vulvovaginal candidiasis (more than 4 attacks per year)
- Non-albicans species
- Abnormal host (e.g. hyperoestrogenic state, diabetes mellitus, immunosuppression)

Diagnosis

In the context of comprehensive sexual health services, routine microscopy and culture is the standard of care for symptomatic women[3;9-13] (Evidence level III, grade C)

A vaginal swab should be taken from the anterior fornix[14] (Evidence level III, grade B) for the following:

- Gram or wet film examination[3;9-13] (Evidence level III, grade B)
- Directly plated to solid fungal media. Speciation to albicans/non-albicans is strongly preferred if uncomplicated disease, and essential if complicated disease suspected/present[15-18] (Evidence level III, grade B)

See British Association of Sexual Health and HIV Clinical Effectiveness Group guidelines 'Sexually Transmitted Infections: UK National Screening and Testing Guidelines', August 2006 for comprehensive guidance.
[www.bashh.org/guidelines/2006/sti_screening_guidelines_v14_0806.pdf]

Management

General Advice
Routine recommendation of use of vulval moisturisers as soap substitute and regular skin conditioner (permission may need to be given to the patient that this does not constitute "internal use").
Avoid tight fitting synthetic clothing[19;20]
Avoid local irritants e.g. perfumed products,
(Level of evidence: IV, grade C)

Treatment
Uncomplicated Vulvovaginal Candidiasis

robertc 28/8/07 11:05
Deleted:

Since all topical and oral azole therapies give a clinical and mycological cure rate of over 80% in uncomplicated acute vulvovaginal candidiasis, choice is a matter of personal preference, availability and affordability.[21;22]
Nystatin preparations give a 70-90% cure rate in this situation.[7]
See later section if severe symptoms/signs.
Topical azole therapies can cause vulvovaginal irritation and this should be considered if symptoms worsen or persist.

Topical Therapies

DRUG	FORMULATION	DOSAGE REGIMEN
Clotrimazole*	Pessary	500mg stat
Clotrimazole*	Pessary	200mg x 3 nights
Clotrimazole*	Pessary	100mg x 6 nights
Clotrimazole*	Vaginal cream (10%)	5g stat
Econazole**	Pessary (Ecostatin 1)	150mg stat
Econazole**	Pessary	150mg x 3 nights
Fenticonazole**	Pessary	600mg stat
Fenticonazole**	Pessary	200mg x 3 nights
Isoconazole*	Vaginal tablet	300mg x 2 stat
Miconazole**	Ovule	1.2g stat
Miconazole**	Pessary	100mg x 14 nights
Nystatin	Vaginal cream (100,000 units)	4g x 14 nights
Nystatin	Pessary (100,000 units)	1-2 x 14 nights

*Effect on latex condoms and diaphragms not known
**Product damages latex condoms and diaphragms

Oral Therapies

DRUG	FORMULATION	DOSAGE REGIMEN
Fluconazole*	Capsule	150mg stat
Itraconazole*	Capsule	200mg bd x 1 day

*Avoid in pregnancy/risk of pregnancy and breastfeeding

(Level of evidence: II, grade A[7;21;22])

Sexual Partners

There is no evidence to support the treatment of asymptomatic male sexual partners in either episodic or recurrent vulvovaginal candidiasis.[23;24]
(Level of evidence: I, grade A)

Follow-up

Unnecessary if symptoms resolve. Test of cure is unnecessary.

Complicated Vulvovaginal Candidiasis

Pregnancy

Asymptomatic colonization with *Candida species* is more common (30-40%)[25] and symptomatic candidosis is more prevalent throughout pregnancy.
Colonisation with *Candida species* is not associated with low birth weight or premature delivery.[26]

Treatment

Topical imidazoles should be used for symptomatic vulvovaginal candidiasis in pregnancy. There is no evidence to suggest asymptomatic women need to be treated.[27]
There is no evidence that any one topical imidazole is more effective than another.
Longer courses are recommended; a four day course will cure just over 50% whereas a seven day course cures over 90%.[27]
Oral therapy is contraindicated.
(Level of evidence: II, grade B[27])

Recurrent Vulvovaginal Candidiasis

Definition

- At least 4 documented episodes of symptomatic vulvovaginal candidiasis annually[8],with at least partial resolution of symptoms between episodes
- Positive microscopy or a moderate/heavy growth of *C albicans* should be documented on at least two occasions when symptomatic

(Level of evidence: IV, grade C)

Prevalence

Approximately 5% of women of reproductive age with a primary episode of vulvovaginal candidiasis will develop recurrent disease.[28;29]

Unknown
Field Code Changed

Pathogenesis

Caused by host factors rather than a more virulent strain or reintroduction of the organism to the genital tract.[30] It is usually due to *C albicans*.

Unknown
Field Code Changed

Host factors include persistence of Candida (as detected by PCR although culture-negative between attacks)[31], uncontrolled diabetes mellitus, immunosuppression, hyperoestrogenaemia (including HRT and the combined oral contraceptive pill),[19;25] disturbance of vaginal flora e.g. through use of broad-spectrum antibiotics,[19;32] and a link to allergy (in particular allergic rhinitis)[33] and pro-inflammatory genetic markers.

Unknown
Field Code Changed

There is no evidence that iron deficiency is implicated.[34]
One study[34] reported a statistically significantly lower serum level of zinc, magnesium and calcium in patients with recurrent vulvovaginal candidiasis, although all levels were within the normal range; other studies have refuted the link with serum zinc levels.[35]

Further Investigation

Speciated fungal culture

FBC, random blood glucose only if other indicators (Level of evidence: IV, grade C)

robertc 28/8/07 11:10
Deleted:

General Advice

- As per uncomplicated disease.
- Vulval emollients may give symptomatic relief as vulval dermatitis both secondary and primary is commonly present.
- Review contraception. Avoid high-oestrogen contraceptives. Low oestrogen pills do not highly predispose to vulvovaginal candidiasis but may possibly have a negative influence on relapsing episodes[36].
- Consider use of Depo-Provera[37].
  (Grade of evidence: III, grade B)
- Lack of evidence for desogestrel-only pill (Cerazette) but would be logical alternative. (Grade of evidence: IV, grade C)

Treatment

The principle of therapy involves an induction regimen to ensure clinical remission, followed immediately by a maintenance regimen.

Recommended Regimen

TREATMENT STAGE	DRUG	FORMULATION	DOSAGE REGIMEN
Induction	Fluconazole*	Capsule	150mg every 72 hours x 3 doses
Maintenance	Fluconazole*	Capsule	150mg once a week for 6 months

*Avoid in pregnancy/ risk of pregnancy and breastfeeding

Approximately 90% of women will remain disease-free at 6 months and 40% at 1 year.
(Level of evidence: Ib, grade A[38])

Alternative Regimens
Induction
Topical imidazole therapy can be increased to 10-14 days according to symptomatic response.
(Level of evidence: IV, grade C)

Maintenance

DRUG	FORMULATION	DOSAGE REGIMEN
Clotrimazole	Pessary	500mg once a week
Fluconazole*	Capsule	50mg daily
Itraconazole*	Capsule	50-100mg daily
Ketoconazole*	Capsule	100mg daily

*Avoid in pregnancy/risk of pregnancy and breastfeeding

Cautions:

- Risk (low) of idiosyncratic drug-induced hepatitis, particularly with itraconazole and ketoconazole.
- These regimens are unlicenced for the indication.
- Anecdotal reports of oral contraceptive failure with prolonged oral azole therapy.

Maintenance therapy should last six months; 90% of women should remain disease-free during treatment.
(Level of evidence: IIa, grade B[39-41])

If relapse between doses consider twice-weekly 150mg fluconazole or 50mg fluconazole daily.
(Level of evidence: IV, grade C)
Alternatively consider the addition of cetirizine 10mg od.[42]

There are no trials addressing the optimal duration of suppressive therapy. If recurrences after maintenance regimen are infrequent, each episode should be treated independently. If recurrent disease is re-established the induction and maintenance regimens should be repeated.
(Level of evidence: IV, grade C)

Alternative Treatments

Probiotics/Lactobacillus

Evidence does not support use of oral or vaginal lactobacillus for the prevention of vulvovaginal candidiasis.[43;44] Adverse effects from their use are extremely infrequent however and there are anecdotal reports of benefit. The mode of action might be via modulation of inflammatory processes[45] rather than due to a competitive effect with candida.

Diet

There is insufficient evidence to make any dietary recommendations, including on carbohydrate or yeast intake.[8;46]

Role of Allergy

Zafirlukast 20mg bd for 6 months[47] may induce remission. Zafirlukast may be considered as maintenance prophylaxis for recurrent vulvovaginal candidiasis, particularly in women with a history of atopy.[42] Cetirizine 10mg daily for 6 months[42] may

cause remission in women who fail to get complete resolution of symptoms with suppressive fluconazole.
(Level of evidence: IIb, grade B)

Tea tree oil (and other essential oils)
Are antifungal in vitro[48-50] but may cause hypersensitivity reactions.[51] Insufficient evidence to recommend use in recurrent vulvovaginal candidiasis.

Severe Vulvovaginal Candidiasis

Regardless of a history of recurrence, fluconazole 150mg should be repeated after three days as this improves symptomatic response but not recurrence.[52]
(Level of evidence: Ib, grade A).

David White 24/12/07 14:04
Deleted:

There is no benefit of 7 day local treatment over a single oral dose of fluconzole.[53] so if oral treatment is contra-indicated it is more logical to repeat a single dose pessary after three days.
(Level of evidence: IV, grade C)
Low-potency corticosteroids are also thought by some experts to improve symptomatic relief in conjunction with adequate antifungal therapy
(Level of evidence: IV, grade C)[8]

Diabetes Mellitus
Symptomatic vulvovaginal candidiasis is more prevalent in diabetics and most problematic in those with poor control.
Increased prevalence of species other than *C albicans*, in particular *C glabrata*.[54;55]
Glycaemic control should be optimized.
When C albicans is isolated, single-dose fluconazole (150mg) gives a similar response to non-diabetics.[55]
(Level of evidence: IIb, grade B)
Symptomatic women with C glabrata isolated: boric acid 600mg intravaginal suppository once a day for 14 days is as effective as fluconazole 150mgs stat[56]
(Level of evidence: Ib, grade A)

HIV Infection

Vulvovaginal candidiasis occurs more frequently and with greater persistence in HIV-infected women.[57]
Treat by conventional methods including use of suppressive antifungal regimens if necessary.[58]
(Level of evidence: III, grade B)

Non-*Albicans* Species
Majority are *Candida glabrata* and are still susceptible to available azoles[59] although most non-*albicans* species have higher MICs. *Candida krusei* is intrinsically resistant to fluconazole.[60]

In general for non-albicans infection longer courses may be needed although there is no data on optimum duration; two weeks is suggested. There no comparative evidence for different treatments. Suggested alternatives include:

Nystatin pessaries are the only licensed alternative to azole therapy and are therefore the usual first line treatment for non-albicans infection. Unfortunately there are ongoing problems with supply (June 2008) and in this case consider local pharmacy production of Amphotericin B vaginal suppositories 50mg once a day for 14 days which is has a 70% success rate.[61]
(Level of evidence: III, grade B)

Boric acid vaginal suppositories 600mg daily for 2-3 weeks.[59;62]
If mucosal irritation occurs the dose can be reduced to 300mg daily.[63] There is still limited evidence for this drug. There may be a teratogenic risk.[64]
(Level of evidence: III, grade B)

Intravaginal flucytosine (5g cream or 1g pessary) either separately[59;65] or with amphotericin[65] to reduce the chances of resistance (for which there is a low genetic barrier) can be used for two weeks.
(Level of evidence: III, grade B)

Qualifying statement

The recommendations in this guideline may not be appropriate for use in all clinical situations. Decisions to follow these recommendations

must be based on the professional judgment of the clinician and consideration of individual patient circumstances and available resources.

All possible care has been taken to ensure the publication of the correct dosage of medication and route of administration. However, it remains the responsibility of the prescribing physician to ensure the accuracy and appropriateness of the medication they prescribe.

Applicability

The diagnosis of VVC is syndromic. Diagnostic criteria may therefore vary with the clinical setting. It is acknowledged that some tests, e.g. for precise speciation of *Candida*, may not be available in all settings.

Some preparations e.g. flucytosine cream may not be available on local formularies. It is advised that such preparations are discussed with the unit pharmacist prior to prescribing.

Auditable Outcome Measures

- Cheapest acceptable topical/oral treatment option to be used in non-pregnant women. Target: 80%.
- All women with severe symptoms should receive fluconazole 150mg repeated after 3 days (unless contraindicated). Target: 100%
- All women with proven recurrent vulvovaginal candidiasis should be offered suppressive or alternative long term therapy. Target: 100%
- Asymptomatic male partners should not be treated. Target: 100%.

Question: 1 of 23

A 29-year-old junior doctor comes to the Emergency Department complaining of a severe headache and neck stiffness. He has had mild diarrhoea over the past few days, and some coryzal symptoms. On examination his BP is 155/82, his pulse is 85 and regular and his temperature is 37.8℃. He has signs consistent with severe meningism but there are no skin rashes or other signs of vasculitis.

Investigations:

Haemoglobin	13.8 g/dl	(13.5-17.7)
White cells	8.9 x 10^9/l	(4-11)
Platelet	183 x 10^9/l	(150-400)
Sodium	141 mmol/	(135-146)
Potassium	4.4 mmol/l	(3.5-5)
Creatinine	92 micromol/l	(79-118)

Lumbar puncture - lymphocytosis, slightly raised protein, normal glucose

Which of the following is the most likely diagnosis?

(Please select 1 option)

- **A** Cytomegalovirus meningitis
- **B** Enterovirus meningitis
- **C** Herpes simplex encephalitis
- **D** Meningococcal meningitis
- **E** Subarachnoid haemorrhage

Work Smart Session - MRCP Part 1

Time taken: 23 mins 22 secs

Question: 10 of 23

A 17-year-old presents to the emergency department with facial and periorbital oedema. This is the third episode over the past two years, and on each of the previous two occasions the problem has been treated with oral corticosteroids.

On examination he has periorbital and bilateral lower limb pitting oedema. His BP is 125/72 mmHg, pulse is 72 and regular. He has no significant findings on auscultation of the chest.

Investigations show:

Haemoglobin	12.5 g/dl	(13.5-17.7)
White cell count	5.0 x 10^9/l	(4-11)
Platelets	260 x 10^9/l	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.2 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(79-118)
Albumin	24 g/l	(35-50)
Urine	Protein +++	

Which of the following is the most appropriate initial way to treat him?

(Please select 1 option)

- ○ Admit for methylprednisolone and cyclophosphamide
- ○ Observe

two years, and on each of the previous two occasions the problem has been treated with oral corticosteroids.

On examination he has periorbital and bilateral lower limb pitting oedema. His BP is 125/72 mmHg, pulse is 72 and regular. He has no significant findings on auscultation of the chest.

Investigations show:

Haemoglobin	12.5 g/dl	(13.5-17.7)
White cell count	5.0 x 10^9/l	(4-11)
Platelets	260 x 10^9/l	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.2 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(79-118)
Albumin	24 g/l	(35-50)
Urine	Protein +++	

Which of the following is the most appropriate initial way to treat him?

(Please select 1 option)

- ○ Admit for methylprednisolone and cyclophosphamide
- ○ Observe
- ○ Prednisolone 10 mg/day for six weeks
- ○ Prednisolone 60 mg/day for six weeks
- ○ Trial of ramipril

Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.2 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(79-118)
Albumin	24 g/l	(35-50)
Urine	Protein +++	

Which of the following is the most appropriate initial way to treat him?

(Please select 1 option)

- ○ Admit for methylprednisolone and cyclophosphamide
- ○ Observe
- ○ Prednisolone 10 mg/day for six weeks
- ◉ Prednisolone 60 mg/day for six weeks ✓ Correct
- ○ Trial of ramipril

The repeated cycles of corticosteroid responsive nephrotic syndrome suggest that this individual has minimal change disease. Therefore he is likely once again to respond to high dose prednisolone, with a tapering dose after the first six weeks of therapy.

In patients who fail to respond initially to corticosteroids, cyclophosphamide and chlorambucil are optional second line agents.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 52-year-old man has a history of hypertension, managed with amlodipine and indapamide. His GP recently tried to commence ramipril, but had to curtail this as his creatinine rose from 129 to 194 after one week of therapy.

He smokes 20 cigarettes per day and is a vasculopath having suffered a transient ischaemic attack (TIA) one year earlier.

On examination in the clinic his BP is 155/92 mmHg, pulse is regular at 80 and a left carotid bruit is audible.

Investigations:

Haemoglobin	12.0 g/dl	(13.5-17.7)
White cell count	6.0 x 10^9/l	(4-11)
Platelets	288 x 10^9/l	(150-400)
Serum sodium	140 mmol/l	(135-146)
Serum potassium	4.0 mmol/l	(3.5-5)
Creatinine	122 µmol/l	(79-118)
Ultrasound scan	Right kidney smaller than the left	
Renal MRA	Suggestive of 80% right renal artery stenosis	

Which of the following is the most appropriate next step in his management?

(Please select 1 option)

- **A** Add bisoprolol to his anti-hypertensive regimen
- **B** Re-introduce low dose ramipril to his regimen
- **C** Refer for urgent angioplasty and stenting
- **D** Refer for vascular surgery
- **E** Trial valsartan as an alternative to ACE inhibition

Creatinine	122 µmol/l	(79-118)
Ultrasound scan	Right kidney smaller than the left	
Renal MRA	Suggestive of 80% right renal artery stenosis	

Which of the following is the most appropriate next step in his management?

(Please select 1 option)

- **A** Add bisoprolol to his anti-hypertensive regimen ← This is the correct answer
- **B** Re-introduce low dose ramipril to his regimen
- **C** Refer for urgent angioplasty and stenting ✕ Incorrect answer selected
- **D** Refer for vascular surgery
- **E** Trial valsartan as an alternative to ACE inhibition

There is considerable debate about the success of angioplasty/stenting or vascular surgery in patients with atherosclerotic renal artery stenosis and difficult to manage hypertension. The most recent study by Bax et al showed no difference in outcomes between those patients managed with medical therapy versus stenting.

Other studies suggest that complications of stenting or angioplasty outweigh any benefits versus medical therapy.

There is no evidence to support re-introducing ACE inhibition or substituting an angiotensin receptor blocker (ARB) with respect to potential outcomes. As such, in the first instance, response to increased medical therapy for blood pressure should be assessed.

Reference:
Bax L, Woittiez AJ, Kouwenberg HJ et al. (2009) Stent placement in patients with atherosclerotic renal artery stenosis and impaired renal function: a randomized trial. Ann Intern Med. 150(12): 840-848

Question: 12 of 23

A 17-year-old girl, who works at a petting zoo, presents with a headache and vomiting to the emergency department. Apparently she suffered a severe diarrhoeal illness which began a few days ago, and she is now passing diarrhoea mixed with blood and mucus.

She has no past history of note, and her only medication is the oral contraceptive pill.

On examination she looks unwell, her BP is 155/92 mmHg and she is pyrexial at 38.2°C. Her abdomen is soft and diffusely tender with very active bowel sounds.

Investigations reveal:

Haemoglobin	10.0 g/dl	(11.5-16.5)
White cell count	11.6 x 10^9/l	(4-11)
Platelets	50 x 10^9/l	(150-400)
Serum sodium	139 mmol/l	(135-146)
Serum potassium	6.0 mmol/l	(3.5-5)
Creatinine	295 µmol/l	(79-118)

What do expect to find on the blood film?

(Please select 1 option)

- **A** Decreased reticulocytes
- **B** Increased lymphocytes
- **C** Increased ghost cells
- **D** Increased schistocytes
- **E** Increased spherocytes

Haemoglobin	10.0 g/dl	(11.5-16.5)
White cell count	11.6 x 10^9/l	(4-11)
Platelets	50 x 10^9/l	(150-400)
Serum sodium	139 mmol/l	(135-146)
Serum potassium	6.0 mmol/l	(3.5-5)
Creatinine	295 µmol/l	(79-118)

What do expect to find on the blood film?

(Please select 1 option)

- A Decreased reticulocytes
- B Increased lymphocytes
- C Increased ghost cells
- **D** Increased schistocytes ✓ Correct
- E Increased spherocytes

This patient has a history consistent with *Escherichia coli* 157 infection, and a picture of haemolytic uraemic syndrome (HUS).

The hallmark of HUS is the appearance of schistocytes (fragmented, deformed, irregular, or helmet shaped red cells) on the blood film. Despite the low platelet count, petechiae and purpura are rarely seen, although GI bleeding is often noted.

Treatment is generally supportive. Non-steroidal anti-inflammatory drugs and anti-diarrhoeals should be avoided, and there is no evidence for the use of antibiotics in the condition.

Question: 13 of 23

A 67-year-old man with chronic renal failure, who uses peritoneal dialysis, presents to the renal ward with a cloudy bag. This is his first episode of continuous ambulatory peritoneal dialysis (CAPD) peritonitis in over two years of dialysing.

He has type 1 diabetes, which precipitated his renal impairment. On examination, he is pyrexial at 38.2°C. His abdomen is diffusely tender, although he has bowel sounds on auscultation.

Investigations showed:

Haemoglobin	10.2 g/dl	(13.5-17.7)
White cell count	13.6 x 10^9/l	(4-11)
Platelets	270 x 10^9/l	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.3 mmol/l	(3.5-5)
Creatinine	346 µmol/l	(79-118)
Dialysis fluid	>100 white cells per mm^3	

Which of the following is the most likely infecting organism?

(Please select 1 option)

- **A** *B. fragilis*
- **B** *Bacteroides spp*
- **C** *P. aeruginosa*
- **D** *S. aureus*
- **E** *S. pyogenes*

White cell count	13.6 x 10^9/l	(4-11)
Platelets	270 x 10^9/l	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.3 mmol/l	(3.5-5)
Creatinine	346 µmol/l	(79-118)
Dialysis fluid	>100 white cells per mm^3	

Which of the following is the most likely infecting organism?

(Please select 1 option)

- A *B. fragilis*
- B *Bacteroides spp*
- C *P. aeruginosa*
- D *S. aureus* ✓ Correct
- E *S. pyogenes*

S. aureus and *S. epidermidis* are the two commonest pathogens identified in cases of CAPD peritonitis.

Various treatment regimes exist, but the majority involve intraperitoneal vancomycin and an oral quinolone. Once culture results are received, the regime can then be tailored appropriately.

The key to avoiding long term complications of CAPD peritonitis is prompt intervention to avoid chronic colonisation of the CAPD catheter and adhesion formation, which prevents adequate fluid exchange.

Question: 14 of 23

A 50-year-old man is admitted to hospital with a third attack of renal stones in the last six months. He suffers from Crohn's disease and has previously had a limited small bowel resection, but his disease is now quiescent.

On examination his BP is 115/72 mmHg, his BMI is 19.5 kg/m^2, and he has a midline scar consistent with a previous laparotomy.

Investigations:

Haemoglobin	12.0 g/dl	(13.5-17.7)
White cell count	5.9 x 10^9/l	(4-11)
Platelets	172 x 10^9/l	(150-400)
Serum sodium	139 mmol/l	(135-146)
Serum potassium	3.9 mmol/l	(3.5-5)
Creatinine	133 µmol/l	(79-118)
24 hour urinary oxalate excretion	Increased	

Which of the following is likely to be the most effective and appropriate intervention?

(Please select 1 option)

- **A** Increase fluid intake
- **B** Reduce dietary calcium intake
- **C** Reduce intake of offal
- **D** Start bendroflumethiazide
- **E** Start furosemide

Haemoglobin	12.0 g/dl	(13.5-17.7)
White cell count	5.9 x 10^9/l	(4-11)
Platelets	172 x 10^9/l	(150-400)
Serum sodium	139 mmol/l	(135-146)
Serum potassium	3.9 mmol/l	(3.5-5)
Creatinine	133 µmol/l	(79-118)
24 hour urinary oxalate excretion	Increased	

Which of the following is likely to be the most effective and appropriate intervention?

(Please select 1 option)

- **A** Increase fluid intake ← This is the correct answer
- **B** Reduce dietary calcium intake
- **C** Reduce intake of offal
- **D** Start bendroflumethiazide ✗ Incorrect answer selected
- **E** Start furosemide

Reducing intake of offal is most helpful at reducing urate excretion; foods such as chocolate, rhubarb and nuts are high in oxalate. One contributor to this patient's increased oxalate excretion is undoubtedly his partial small bowel resection, and increasing dietary calcium intake decreases urinary oxalate excretion.

Therefore the most effective and appropriate intervention from those given is to increase his oral fluid intake significantly.

Question: 15 of 23

A 21-year-old woman presents to the clinic after her fifth episode of nephrolithiasis in the past three years. She tells you that both her brother and father also suffer from renal stones.

On examination her BP is 135/80 mmHg. General physical examination is entirely normal.

Investigations show:

Haemoglobin	12.0 g/dl	(11.5-16.5)
White cell count	6.4 x 10^9/l	(4-11)
Platelets	272 x 10^9/l	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.1 mmol/l	(3.5-5)
Creatinine	85 µmol/l	(79-118)
Calcium	2.89 mmol/l	(2.20-2.67)
PTH	Upper limit of normal range	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- **A** Familial hypocalciuric hypercalcaemia
- **B** Primary hyperparathyroidism
- **C** PTHrP levels increased due to underlying malignancy
- **D** Secondary hyperparathyroidism
- **E** Tertiary hyperparathyroidism

Platelets	272 x 10^9/l	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.1 mmol/l	(3.5-5)
Creatinine	85 µmol/l	(79-118)
Calcium	2.89 mmol/l	(2.20-2.67)
PTH	Upper limit of normal range	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- **A** Familial hypocalciuric hypercalcaemia ✓ Correct
- **B** Primary hyperparathyroidism
- **C** PTHrP levels increased due to underlying malignancy
- **D** Secondary hyperparathyroidism
- **E** Tertiary hyperparathyroidism

The strong family history points towards this autosomal dominant condition as being the most likely diagnosis. Most often it leads to asymptomatic elevated levels of serum calcium, although some patients with the condition may suffer recurrent episodes of renal stones.

The inherited condition is caused by a mutation in the calcium sensing receptor (CASR) gene, which encodes a calcium-sensing receptor expressed in the parathyroid gland and kidneys. The perceived lack of calcium levels by the parathyroid leads to normal to high levels of parathyroid hormone and therefore hypercalcaemia.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 62-year-old man attends a clinic complaining of progressive peripheral oedema, which has got to the stage where by the end of the day he is hardly able to wear his shoes. He has a past history of hypertension which is managed with amlodipine, but nil else of note.

On examination his BP is 155/85 mmHg. His pulse is 78 and regular. His heart sounds are normal and his chest is clear. He has gross pitting oedema to mid shin on both lower limbs.

Haemoglobin	13.9 g/dl	(13.5-17.7)
White cell count	7.6 x 10^9/L	(4-11)
Platelets	290 x 10^9/L	(150-400)
Serum sodium	140 mmol/l	(135-146)
Serum potassium	4.0 mmol/l	(3.5-5)
Creatinine	135 µmol/l	(79-118)
Albumin	24 g/l	(35-50)
Urinary protein	3.5 g/24 hr	

Renal biopsy: Thickened renal capillary walls seen on biopsy, but with patent lumina.

Which of the following treatments is most likely to affect this patient's prognosis?

(Please select 1 option)

- **A** Cyclophosphamide
- **B** Prednisolone
- **C** Ramipril
- **D** Rituximab
- **E** Simvastatin

Serum potassium	4.0 mmol/l	(3.5-5)
Creatinine	135 µmol/l	(79-118)
Albumin	24 g/l	(35-50)
Urinary protein	3.5 g/24 hr	

Renal biopsy: Thickened renal capillary walls seen on biopsy, but with patent lumina.

Which of the following treatments is most likely to affect this patient's prognosis?

(Please select 1 option)

- **A** Cyclophosphamide
- **B** Prednisolone ✕ Incorrect answer selected
- **C** Ramipril ← This is the correct answer
- **D** Rituximab
- **E** Simvastatin

Corticosteroids alone are ineffective in the treatment of membranous nephropathy. A study of alternating monthly treatment with chlorambucil and steroids did suggest some benefit but this is open to debate and has been disputed in a number of review articles.

Rituximab, a B-cell depleting anti-CD20 chimeric monoclonal antibody has shown some benefit in a small proof of concept study, although it is unlikely to be appropriate for widespread use.

In contrast, ramipril is proven to affect both proteinuria and hypertension in patients with a diagnosis of membranous nephropathy, and is therefore the backbone of therapy for this condition.

Question: 17 of 23

A 49-year-old owner of a pub is admitted in a confused and agitated state. He has recently tried to stop drinking and according to his wife it is 24 hours since his last drink.

When you see him his BP is elevated at 155/90 mmHg, pulse at 90, and he looks agitated. There are signs of chronic liver disease on physical examination. He is trying to pull the sheets over his head as he tells you he can see a large dog in the next bed.

Investigations show

Haemoglobin	10.9 g/dl	(13.5-18)
White cell count	8.2 x 10^9/l	(4-10)
Platelets	190 x 10^9/l	(150-400)
Sodium	139 mmol/l	(134-143)
Potassium	4.3 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(60-120)
Glucose	4.5 mmol/l	(3.6-5.8)
ALT	190 IU/l	(5-60)

Which of the following is the most likely diagnosis?

(Please select 1 option)

- ○ Alcoholic hallucinosis
- ○ Delirium tremens
- ○ Hypomania
- ○ Schizophrenia
- ○ Wernicke's encephalopathy

Sodium	139 mmol/l	(134-143)
Potassium	4.3 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(60-120)
Glucose	4.5 mmol/l	(3.6-5.8)
ALT	190 IU/l	(5-60)

Which of the following is the most likely diagnosis?

(Please select 1 option)

- Alcoholic hallucinosis ← This is the correct answer
- Delirium tremens ✕ Incorrect answer selected
- Hypomania
- Schizophrenia
- Wernicke's encephalopathy

As many as 25% of habitual alcohol drinkers may suffer from alcoholic hallucinosis when they withdraw from alcohol for 24 hours or longer. Hallucinations are usually visual or tactile, but may be auditory and persecutory.

Delirium tremens is associated with a much more profound disorientation and agitation, with severe autonomic dysfunction and cardiovascular collapse. It may well be preceded by alcohol withdrawal seizures.

Management of this patient involves B vitamin replacement with a preparation such as pabrinex, and the use of appropriate withdrawal medication.

Work Smart Session - MRCP Part 1

Time taken: 47 mins 48 secs

Question: 18 of 23

Which of the following are characteristic electrocardiogram (ECG) features of hypokalaemia?

(Please select 1 option)

○	Flattened p waves
○	ST elevation
◉	U waves ✓ Correct
○	Ventricular tachycardia
○	Wide QRS

U waves are characteristic features of hypokalaemia.

Further ECG features of hypokalaemia include ST depression, low amplitude T waves and ventricular fibrillation.

Ventricular tachycardia is thought to be exceedingly rare in hypokalaemia.

The remaining answers are ECG findings typical of hyperkalaemia, together with absent P waves, tall tented t waves, asystole and ventricular fibrillation.

Work Smart Session - MRCP Part 1

Time taken: 47 mins 48 secs

Question: 19 of 23

A 32-year-old female smoker presents with acute severe asthma. The SaO2 are 80% on 15 L of oxygen and the pO2 is 8.2kPa (10.5-13).

There is widespread expiratory wheeze throughout the chest. She is given IV hydrocortisone, 100% oxygen and 5 mg of nebulised salbutamol.

What is the next step in your management?

(Please select 1 option)

- IV augmentin
- IV magnesium
- IV potassium
- IV theophylline
- Oral prednisolone

(Please select 1 option)

○	IV augmentin
○	IV magnesium ← This is the correct answer
○	IV potassium
◉	IV theophylline ✕ Incorrect answer selected
○	Oral prednisolone

This question focuses on acute treatment of asthma.

Your initial approach should be SOS - salbutamol, oxygen and steroids intravenously (IV).

In the meantime a chest x-ray (CXR) should be organised to rule out pneumothorax.

You should then consider further efforts to treat bronchoconstriction - a silent chest, or a tiring patient should suggest ITU review.

The recommended dose of magnesium is 2 g over 30 minutes. The mechanism by which it has its effect is not fully understood, but it is thought that low magnesium levels in bronchial smooth muscle favour bronchoconstriction.

IV theophylline may be considered, but magnesium would be higher on the list.

IV antibiotic may be indicated, but your initial focus should be promoting bronchodilation.

IV potassium may be required as the beta agonists push down the potassium.

Oral prednisolone can wait, as you have already given IV hydrocortisone as part of your SOS approach.

Haemoglobin	13.8 g/dl	(13.5-17.7)
White cells	8.9 x 10^9/l	(4-11)
Platelet	183 x 10^9/l	(150-400)
Sodium	141 mmol/	(135-146)
Potassium	4.4 mmol/l	(3.5-5)
Creatinine	92 micromol/l	(79-118)

Lumbar puncture - lymphocytosis, slightly raised protein, normal glucose

Which of the following is the most likely diagnosis?

(Please select 1 option)

- A Cytomegalovirus meningitis
- **B** Enterovirus meningitis ✓ Correct
- C Herpes simplex encephalitis
- D Meningococcal meningitis
- E Subarachnoid haemorrhage

The answer is B), enterovirus meningitis. Enterovirus is the commonest cause of viral meningitis in the adult population. The corizal symptoms coupled with a mild diarrhoeal illness fit with this picture, as do the lumbar puncture findings. Management of viral meningitis is conservative, with adequate hydration and analgesia.

Work Smart Session - MRCP Part 1

Time taken: 49 mins 21 secs

Question: 20 of 23

A 27-year-old lady presents with generalised oedema of five months duration.

Investigations reveal proteinuria (5.5 g/day), hypoproteinaemia and hypercholesterolaemia, urea 10 mmol/L (2.5-7.5) and creatinine 200 mol/L (60-110). Renal biopsy confirms membranous glomerulonephritis.

What will be the most appropriate management to get remission?

(Please select 1 option)

- Azathiaprine
- Cyclophosphamide plus methylprednisolone
- Cyclosporin A
- Methylprednisolone
- Protein restriction

A 27-year-old lady presents with generalised oedema of five months duration.

Investigations reveal proteinuria (5.5 g/day), hypoproteinaemia and hypercholesterolaemia, urea 10 mmol/L (2.5-7.5) and creatinine 200 mol/L (60-110). Renal biopsy confirms membranous glomerulonephritis.

What will be the most appropriate management to get remission?

(Please select 1 option)

○	Azathiaprine
◉	Cyclophosphamide plus methylprednisolone ✓ Correct
○	Cyclosporin A
○	Methylprednisolone
○	Protein restriction

The twin aims of treating membranous nephropathy are

- First to induce a remission of the nephrotic syndrome and
- Second to prevent the development of end stage renal failure.

A meta-analysis of four randomised controlled studies comparing treatments of membranous nephropathy showed that regimes comprising chlorambucil or cyclophosphamide, either alone or with steroids, were more effective than symptomatic treatment or treatment with steroids alone in inducing remission of the nephrotic syndrome.

A small randomised controlled study of 17 patients with a persistent nephrotic syndrome and declining renal function suggested that ciclosporin A slowed the rate of decline of renal function: this requires confirmation in a larger trial.

Work Smart Session - MRCP Part 1

Time taken: 51 mins 22 secs

Question: 21 of 23

A 31-year-old female in her third pregnancy is receiving low molecular weight heparin (LMWH) at treatment doses due to a pulmonary embolism three months prior to conception. She is currently at 31 weeks gestation.

All fetal scans have been normal, and her blood pressure is 126/80 mmHg in the left lateral position.

Which of the following statements is correct?

(Please select 1 option)

- Breastfeeding is not advised
- Clexane treatment needs no monitoring in pregnancy
- It is safe for her to receive NSAIDs perinatally
- Prothrombin time is an indicator of anti-factor Xa activity
- The dose of Clexane should be increased in the third trimester

Question: 21 of 23

A 31-year-old female in her third pregnancy is receiving low molecular weight heparin (LMWH) at treatment doses due to a pulmonary embolism three months prior to conception. She is currently at 31 weeks gestation.

All fetal scans have been normal, and her blood pressure is 126/80 mmHg in the left lateral position.

Which of the following statements is correct?

(Please select 1 option)

○	Breastfeeding is not advised ← This is the correct answer
○	Clexane treatment needs no monitoring in pregnancy
○	It is safe for her to receive NSAIDs perinatally
○	Prothrombin time is an indicator of anti-factor Xa activity
◉	The dose of Clexane should be increased in the third trimester ✕ Incorrect answer selected

There is no recommendation that the dose of LMWH should be increased in the third trimester.

Increases in prothrombin time and activated clotting time (ACT) are not linearly correlated with increasing LMWH anti-thrombotic activity and therefore are unsuitable and unreliable for monitoring LMWH activity.

Nonsteroidal antiinflammatory drug (NSAID) treatment increases the risk of haemorrhage in both mother and fetus.

It is not known whether unchanged enoxaparin sodium is excreted in human breast milk. The oral absorption of enoxaparin sodium is unlikely. However, as a precaution, lactating mothers receiving enoxaparin sodium should be advised to avoid breast feeding.

Work Smart Session - MRCP Part 1

Time taken: 53 mins 5 secs

Question: 22 of 23

A 40-year-old male presents to casualty with weakness and parasthesiae of the right arm and leg. The symptoms developed 12 hours after the onset of a piercing left sided headache. There is no neck stiffness, but there is a pain in the left side of the neck and occiput. Kernig's sign is negative. The patient is afebrile, and blood results are normal.

What is the investigation of choice?

(Please select 1 option)

- Contrast arteriography
- CT head
- Duplex scanning of the neck vessels
- Lumbar puncture
- MRI brain

A 40-year-old male presents to casualty with weakness and parasthesiae of the right arm and leg. The symptoms developed 12 hours after the onset of a piercing left sided headache. There is no neck stiffness, but there is a pain in the left side of the neck and occiput. Kernig's sign is negative. The patient is afebrile, and blood results are normal.

What is the investigation of choice?

(Please select 1 option)

○	Contrast arteriography ← This is the correct answer
◉	CT head ✕ Incorrect answer selected
○	Duplex scanning of the neck vessels
○	Lumbar puncture
○	MRI brain

Ischaemic neurological features (transient or completed strokes) are found in 30-80% of presenting patients presenting with carotid artery dissection. Pulsatile tinnitus is common, as well as syncope and amaurosis fugax. Headache is commonly ipsilateral to the side of the carotid dissection, and recurrence of the headache suggests extension or recurrence of the dissection. The most accurate study and the current gold standard for diagnosis of carotid artery dissection, contrast arteriography should be strongly considered if neurological findings are incompatible with the findings of CT head, there is mono or hemiparesis with normal mental state, signs or history of major cervical trauma with abnormal neurology, or basilar skull fracture in a patient with altered mental status. In the absence of arteriography, Duplex scanning or MRI with MRA may be considered the next best tests. Limitations of duplex scanning include difficulties of scanning the distal internal carotid artery, detecting emboli, and evaluating intracranial arteries. The combination of MRI and MRA is more reliable in detecting dissection than either modality alone. Lumbar puncture results may be misleading, as xanthochromia may occur when a haematoma propagates. This rare finding may lead to a diagnosis of subarachnoid hemorrhage and failure to perform further carotid workup.

Work Smart Session - MRCP Part 1

Time taken: 55 mins 32 secs

Question: 23 of 23

A patient is planning to travel through the southern states of America, but is worried about West Nile virus.

Which of the following statements regarding West Nile virus is correct?

(Please select 1 option)

○	Infection is non-fatal
○	Is a member of the arborvirus family
◉	May be associated with poliomyelitis-like paralysis ✓ Correct
○	Transplacental transmission does not occur
○	Treatment with interferon is effective in West Nile virus encephalitis

Neurological manifestations of West Nile virus include

- A poliomyelitis-like paralysis
- Seizures
- A parkinsonian movement disorder.

West Nile virus is a *Flavivirus* of the Japanese encephalitis family and transplacental transmission has been reported.

In 2003 there were 276 deaths attributed to West Nile virus. Interestingly, West Nile Virus is endemic in the avian population. The deaths of large numbers of birds in an area may thus herald an imminent epidemic of West Nile virus.

Work Smart Session - MRCP Part 1

Time taken: 5 mins 52 secs

Question: 2 of 23

A 42-year-old woman presents to the clinic with a chronic cough. Which of the following features would increase the suspicion that she is suffering from asthma?

(Please select 1 option)

- **A** Associated dizziness
- **B** Chronic cough without wheeze
- **C** Symptoms in response to exercise ← This is the correct answer
- **D** Symptoms corresponding with a cold
- **E** Voice disturbance ✕ Incorrect answer selected

The answer is C), symptoms in response to exercise. Guidelines from BTS/SIGN on the diagnosis of asthma suggest that the presence of wheeze, breathlessness, chest tightness or cough, particularly if symptoms are worse at night or in the early morning, after exercise, allergy exposure or cold air, are suggestive of the diagnosis. A family history of atopy or asthma, personal history of atopy, widespread wheeze, low FEV1 or PEFR also support the diagnosis. Dizziness, light headedness, voice disturbance and chronic cough without wheeze do not support a diagnosis of asthma.

Work Smart Session - MRCP Part 1

Time taken: 5 mins 52 secs

Question: 3 of 23

A 36-year-old single woman with a history of asthma comes to the clinic complaining of symptoms of indigestion.

She uses a steroid inhaler and on examination of her oropharynx you can see obvious evidence of candidiasis. You send her for an endoscopy, which unfortunately reveals extensive oesophageal candidiasis.

Which of the following tests would be most important to consider in this patient?

(Please select 1 option)

- **A** CD4 count
- **B** Complement testing
- **C** Fasting blood glucose
- **D** HIV antibody testing
- **E** Immunoglobulin testing

Work Smart Session - MRCP Part 1

Time taken: 6 mins 47 secs

Question: 3 of 23

A 36-year-old single woman with a history of asthma comes to the clinic complaining of symptoms of indigestion.

She uses a steroid inhaler and on examination of her oropharynx you can see obvious evidence of candidiasis. You send her for an endoscopy, which unfortunately reveals extensive oesophageal candidiasis.

Which of the following tests would be most important to consider in this patient?

(Please select 1 option)

○	**A** CD4 count
○	**B** Complement testing
○	**C** Fasting blood glucose
◉	**D** HIV antibody testing ✓ Correct
○	**E** Immunoglobulin testing

The answer is D, HIV antibody testing.

Whilst candidiasis affecting the oropharynx may be a result of poor inhaler technique and deposition of steroid powder within the mouth, it does not usually result in oesophageal candidiasis. The other possible cause of recurrent oral and genital candida infection is diabetes mellitus, although again this would not normally lead to oesophageal disease.

In the case of this patient, immunocompromise should be suspected and HIV considered, with appropriate pre-test counselling.

A 20-year-old student comes to the clinic complaining of dysuria and minor scrotal swelling and pain. He has also noticed a purulent urethral discharge.

On examination his temperature is 37.5 C, his scrotum is mildly swollen and tender and you can express a mucopurulent discharge from his urethral meatus.

Investigations show:

Haemoglobin	13.9 g/dl	(13.5-17.7)
White cell count	8.8 x 10^9/l	(4-11)
Platelets	269 x 10^9/l	(150-400)
Serum sodium	141 mmol/l	(135-146)
Serum potassium	4.5 mmol/l	(3.5-5)
Creatinine	85 micromol/l	(79-118)
Urinary chlamydial antigen positive		

Which of the following is the most appropriate anti-microbial therapy for him?

(Please select 1 option)

- **A** Azithromycin 1 g as single dose
- **B** Ciprofloxacin 500 mg BD for 7 days
- **C** Minocycline 100 mg daily for 9 days
- **D** Norfloxacin 400 mg daily for 7 days
- **E** Penicillin V 500 mg BD for 7 days

Creatinine	85 micromol/l	(79-118)
Urinary chlamydial antigen positive		

Which of the following is the most appropriate anti-microbial therapy for him?

(Please select 1 option)

- **A** Azithromycin 1 g as single dose ✓ Correct
- **B** Ciprofloxacin 500 mg BD for 7 days
- **C** Minocycline 100 mg daily for 9 days
- **D** Norfloxacin 400 mg daily for 7 days
- **E** Penicillin V 500 mg BD for 7 days

The answer is A, azithromycin 1 g as a single dose.

In a student population where compliance may well be a problem, giving a single dose of antibiotics for the treatment of *Chlamydia* is the most sensible option.

Other options for treatment of *Chlamydia* include minocycline, although doxycycline causes less gastrointestinal disturbance. Ofloxacin 200 mg BD for seven days is also considered a potential option according to SIGN guidelines.

He should also be referred to the GUM clinic for screening for other sexually transmitted infections.

http://www.sign.ac.uk/guidelines/fulltext/42/section4.html

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 44-year-old man is brought to the hospital by his boyfriend.

Over the past few weeks he has complained of increasing headaches and nocturnal fevers. His boyfriend is now concerned that over the weekend he has taken to his bed and has become drowsy and confused.

On examination his temperature is 37.8°C and BP 150/90 mmHg. He has papilloedema and neck stiffness. He refuses to comply with most of the elements of neurological testing.

Investigations show:

Haemoglobin	11.9 g/dl	(13.5-17.7)
White cell count	9.7 x 10^9/l	(4-11)
Platelets	204 x 10^9/l	(150-400)
Serum Sodium	136 mmol/l	(135-146)
Serum Potassium	4.0 mmol/l	(3.5-5)
Creatinine	111 micromol/l	(79-118)
Glucose	6.7 mmol/l	(non fasting)
CSF	opening pressure 22cm water	turbid appearance
Glucose	6.5 mmol/l	india ink test positive
CT scan	Small ventricles but otherwise unremarkable	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- **A** Cryptococcal meningitis
- **B** HIV dementia
- **C** HIV encephalopathy
- **D** Meningococcal meningitis
- **E** Tuberculous meningitis

CSF	opening pressure 22cm water	turbid appearance
Glucose	6.5 mmol/l	india ink test positive
CT scan	Small ventricles but otherwise unremarkable	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- **A** Cryptococcal meningitis ← This is the correct answer
- **B** HIV dementia
- **C** HIV encephalopathy ✕ Incorrect answer selected
- **D** Meningococcal meningitis
- **E** Tuberculous meningitis

The answer is A, cryptococcal meningitis on a background of HIV infection.

The insidious onset seen here, coupled with signs of raised intracranial pressure, normal glucose on CSF sampling and positive india ink test are all strong pointers to the diagnosis of cryptococcal meningitis. India ink smears however are less sensitive and specific than CSF cryptococcal antigen test, which has a sensitivity of greater than 95%, but false negative tests can occur with a low organism burden.

MRI scanning is more sensitive than CT and may show low intensity lesions in the basal ganglia which enhance with gadolinium.

Treatment in this case would be with amphotericin B combined with flucytosine, although good results have also been seen with flucytosine and fluconazole combination therapy.

Despite aggressive intervention however, mortality is still high at around 6%.

© 2011 BMJ Publishing Group Ltd All rights reserved Terms and conditions Privacy policy

A 18-year-old student presents to the student health service with frank haematuria that begun some 48 hours after an upper respiratory tract infection.

On examination he is apyrexial, BP is 110/72 mmHg and pulse is 70. His chest is clear and his abdomen is soft and non-tender.

Investigations reveal:

Haemoglobin	14.0 g/dl	(13.5-17.7)
White cell count	8.0 x 10^9/l	(4-11)
Platelets	248 x 10^9/L	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.3 mmol/l	(3.5-5)
Creatinine	85 micromol/l	(79-118)
Urine blood +++		

Which of the following is the most appropriate way to manage him?

(Please select 1 option)

- **A** Methylprednisolone and cyclophosphamide
- **B** Observation
- **C** Prednisolone 60 mg/day
- **D** ACE inhibitor titrated to maximal tolerated dose
- **E** ACE inhibitor titrated to maximal tolerated dose and ARB in combination

Submit answer | Skip question | Tag Question | Remove question

Serum potassium	4.3 mmol/l	(3.5-5)
Creatinine	85 micromol/l	(79-118)
Urine blood +++		

Which of the following is the most appropriate way to manage him?

(Please select 1 option)

- **A** Methylprednisolone and cyclophosphamide
- **B** Observation ✓ Correct
- **C** Prednisolone 60 mg/day
- **D** ACE inhibitor titrated to maximal tolerated dose
- **E** ACE inhibitor titrated to maximal tolerated dose and ARB in combination

This patient almost certainly has IgA nephropathy, given his presentation with frank haematuria occurring in such close proximity to a recent upper respiratory tract infection.

The findings including normal blood pressure, normal creatinine and haematuria without proteinuria point towards a benign prognosis and for this reason he only requires regular monitoring rather than intervention with immunosuppressive agents.

Treatment with corticosteroids is usually reserved for those patients with hypertension and a rising creatinine.

Where there is significant hypertension +/- proteinuria, then ACE inhibitors are the first choice anti-hypertensive agent.

Post-streptococcus glomerulonephritis usually occurs one to three weeks after initial infection.

Next question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 50-year-old man is admitted to the hospital with a third attack of renal stones in the last six months.

He suffers from Crohn's disease and has previously had a limited small bowel resection, but his disease is now quiescent.

On examination his BP is 115/72 mmHg, his BMI is 19.5, he has a midline scar consistent with a previous laparotomy.

Investigations show:

Haemoglobin	12.0 g/dl	(11.5-16.5)
White cell count	6.4 x 10^9/l	(4-11)
Platelets	272 x 10^9/l	(150-400)
Serum sodium	138 mmol/l	(135-146)
Serum potassium	4.1 mmol/l	(3.5-5)
Creatinine	85 micromol/l	(79-118)
Calcium	2.89 mmol/l	(2.20-2.67)
PTH	Upper limit of normal range	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- **A** Familial hypocalciuric hypercalcaemia
- **B** Primary hyperparathyroidism
- **C** PTHrP levels increased due to underlying malignancy
- **D** Secondary hyperparathyroidism
- **E** Tertiary hyperparathyroidism

Serum potassium	4.1 mmol/l	(3.5-5)
Creatinine	85 micromol/l	(79-118)
Calcium	2.89 mmol/l	(2.20-2.67)
PTH	Upper limit of normal range	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- **A** Familial hypocalciuric hypercalcaemia ← This is the correct answer
- **B** Primary hyperparathyroidism ✕ Incorrect answer selected
- **C** PTHrP levels increased due to underlying malignancy
- **D** Secondary hyperparathyroidism
- **E** Tertiary hyperparathyroidism

There is no evidence of renal failure or malabsorption. Familial hypocalciuric hypercalcaemia is an autosomal dominant condition and this is the most likely diagnosis.

The disease most often leads to asymptomatic elevated levels of serum calcium, although some patients with the condition may suffer recurrent episodes of renal stones.

The inherited condition is caused by a mutation in the calcium sensing receptor (CASR) gene, which encodes a calcium sensing receptor expressed in the parathyroid gland and kidneys.

The perceived lack of calcium levels by the parathyroid leads to normal to high levels of parathyroid hormone and therefore hypercalcaemia.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 49-year-old woman comes to the clinic complaining of rapidly worsening lethargy and nausea. Over the past few days she has become increasingly unwell and is now barely able to get out of the house.

Other symptoms of note include progressive shortness of breath and a cough productive of blood stained sputum. Her only consultations with the doctor over the past six months have been about the shape of her nose; she has suffered some collapse of her nasal bridge and is considering plastic surgery.

On examination you notice collapse of the bridge of her nose, and nasal congestion when she speaks. Her BP is elevated at 155/95 mmHg. You can hear crepitations on auscultation of the chest.

Investigations show:

Haemoglobin	12.0 g/dl	(11.5-16.5)
White cell count	11.6 x 10^9/l	(4-11)
Platelets	202 x 10^9/l	(150-400)
Serum sodium	139 mmol/l	(135-146)
Serum potassium	5.8 mmol/l	(3.5-5)
Creatinine	285 micromol/l	(79-118)
CXR	Patchy interstitial shadowing	
C-ANCA	Positive	

Which of the following is the most appropriate treatment?

(Please select 1 option)

- **A** Infliximab
- **B** Methylprednisolone and azathioprine
- **C** Methylprednisolone and cyclophosphamide
- **D** Methylprednisolone and methotrexate
- **E** Prednisolone

CXR	Patchy interstitial shadowing
C-ANCA	Positive

Which of the following is the most appropriate treatment?

(Please select 1 option)

○	**A** Infliximab
○	**B** Methylprednisolone and azathioprine
○	**C** Methylprednisolone and cyclophosphamide ← This is the correct answer
○	**D** Methylprednisolone and methotrexate
◉	**E** Prednisolone ✕ Incorrect answer selected

Methylprednisolone and cyclophosphamide is the treatment of choice for induction of remission in Wegener's granulomatosis, the obvious diagnosis here.

Evidence from controlled trials suggests that once remission is achieved azathioprine or methotrexate may be reasonable alternatives to cyclophosphamide.

In refractory Wegener's, both infliximab and rituximab have shown some degree of promise.

Prognosis is dependent on prompt diagnosis and early intervention with immunosuppressive therapies, with evidence suggesting that time to diagnosis has shortened over the past few years.

Work Smart Session - MRCP Part 1

Time taken:

Question: 1 of 33

A 35-year-old Nigerian female was assessed in an antenatal clinic. She was clinical well.

Antenatal screening for syphilis revealed the following results:

Treponemal EIA total	Detected
Treponemal EIA IgM	Not detected
Treponemal TPPA	Detected 1:160
Treponemal RPR	Not detected

What is the likely diagnosis?

(Please select 1 option)

- **A** Acute syphilis infection
- **B** Early latent syphilis infection
- **C** Late latent syphilis infection
- **D** Non-specific reactivity
- **E** Yaws

Work Smart Session - MRCP Part 1

Time taken: 29 mins 11 secs

Question: 10 of 33

A 70-year-old male with a preceding history of earache presents to hospital with clinical features consistent with meningitis.

What is the likeliest aetiology?

(Please select 1 option)

○	**A** Influenza
○	**B** Meningitides
○	**C** Monocytogenes
◉	**D** Pneumoniae ✓ Correct
○	**E** Tuberculosis

The preceding history of earache suggests that the meningitis is secondary to otitis media.

Although all the above organisms can cause meningitis, meningitis secondary to otitis media is most likely to be caused by *Streptococcus pneumoniae*.

Work Smart Session - MRCP Part 1

Time taken: 29 mins 55 secs

Question: 11 of 33

A patient with TB is receiving the following drugs as induction phase during treatment; rifampicin, isoniazid, pyrazinamide, ethambutol and pyridoxine. Which drug is most likely to cause peripheral neuropathy?

(Please select 1 option)

○	**A** ethambutol
◉	**B** isoniazid ✓ Correct
○	**C** pyrazinamide
○	**D** pyridoxine
○	**E** rifampicin

Supplementation with pyridoxine, vitamin B6, reduces the risk.

Question: 12 of 33

A patient with multiple drug resistant (MDR) TB is receiving prolonged treatment with moxifloxacin. Which side effect is likely to occur as a result of prolonged administration?

(Please select 1 option)

◉	**A** Achilles tendinitis ✓ Correct
○	**B** Hepatotoxicity
○	**C** Nephrotoxicity
○	**D** Peripheral neuropathy
○	**E** Retinopathy

This is an idiosyncratic reaction associated with prolonged use of quinolones.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 7 mins 25 secs

Question: 13 of 33

Gentamicin, 7mg/kg once daily, is administered to an elderly patient with severe urosepsis. Twenty-four hours post administration gentamicin levels are > 2mg/l, Which of the following complications would you expect?

(Please select 1 option)

○	**A** Hepatotoxicity
◉	**B** Nephrotoxicity ✓ Correct
○	**C** Ototoxicity
○	**D** Peripheral neuropathy
○	**E** Retinopathy

Prolonged exposure to gentamicin is likely to cause nephrotoxicity, particularly in elderly patients with renal impairment. Therefore the next dose of gentamicin should not be given if the gentamicin trough exceeds 2mg/l.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 8 mins 48 secs

Question: 14 of 33

A multiple drug resistant *Escherichia coli* was isolated from the urine of a patient with severe sepsis. What is the likely mechanism of resistance?

(Please select 1 option)

◉	**A** Alteration of drug target ✕ Incorrect answer selected
○	**B** Drug efflux
○	**C** Drug impermeability
○	**D** Extended spectrum beta-lactamase (ESBL) production ← This is the correct answer
○	**E** Penicillinase production

Some *Escherichia coli* isolates produce an ESBL that inactivate second and third generation cephalosporins. The class of drugs that will most reliably treat these infections are the carbapenems.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 11 mins 11 secs

Question: 18 of 33

What is the mechanism of action of gentamicin, when used synergistically with benzylpenicillin to treat an infective endocarditis caused by *Viridans Streptococci*?

(Please select 1 option)

○	**A** Cell wall inhibition
○	**B** Inhibition of protein synthesis (translation) ← This is the correct answer
◉	**C** Inhibition of protein synthesis (transcription) ✕ Incorrect answer selected
○	**D** Inhibition of folic acid metabolism
○	**E** Interference with DNA replication

Gentamicin is synergistic to the action of benzylpenicillin. Benzylpenicillin is bactericidal, inhibiting cell wall synthesis, enabling gentamicin to enter the bacterial cell. It acts at the level of the ribosome, inhibiting protein synthesis.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 12 mins 18 secs

Question: 19 of 33

What is the mechanism of resistance for rifampicin resistant *Mycobacterium tuberculosis*?

(Please select 1 option)

◉	**A** Alteration in cell wall permeability ✕ Incorrect answer selected
○	**B** Alteration of the DNA dependent RNA transcriptase ← This is the correct answer
○	**C** Alteration of penicillin binding proteins (PBP's)
○	**D** Efflux mechanism
○	**E** Production of the inactivating enzyme, penicillinase

Rifampicin is a bacteriostatic antibiotic which acts by inhibiting protein synthesis. Mutations in *rpoB* gene cause alterations in the bacterial DNA dependent RNA transcriptase which prevents the binding of rifampicin.

Treponemal EIA total	Detected
Treponemal EIA IgM	Not detected
Treponemal TPPA	Detected 1:160
Treponemal RPR	Not detected

What is the likely diagnosis?

(Please select 1 option)

- **A** Acute syphilis infection
- **B** Early latent syphilis infection
- **C** Late latent syphilis infection ✓ Correct
- **D** Non-specific reactivity
- **E** Yaws

It is important that the serology is correctly interpreted and, during pregnancy, this lady is referred to a GU clinic for treatment with benzathine penicillin if not previously treated.

The detection of treponemal EIA total is confirmed by treponemal TPPA so this result is not a false positive. As treponemal IgM is not detected this is not consistent with acute infection.

In the absence of symptoms, late latent infection is more likely than early latent infection.

These results are unlikely to be cross reactivity secondary to yaws.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 13 mins

Question: 20 of 33

What is the mechanism of resistance for penicillin resistant *Streptococcus pneumoniae*?

(Please select 1 option)

○	**A** Alteration in cell wall permeability
○	**B** Alteration of the DNA dependent RNA transcriptase
○	**C** Alteration of penicillin binding proteins (PBP's) ← This is the correct answer
○	**D** Efflux
◉	**E** Production of the inactivating enzyme, penicillinase ✕ Incorrect answer selected

Penicillin is a bactericidal antibiotic which acts by inhibiting cell wall synthesis. Mutations in PBP's, enzymes required for cell wall synthesis, result in penicillin resistance.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 13 mins

Question: 21 of 33

A patient is diagnosed with an abnormality of oligopeptide disposal.

Which intracellular organelle is associated with the metabolism of oligopeptides?

(Please select 1 option)

- Golgi apparatus
- Lysosomes
- Peroxisomes
- Ribosomes
- Smooth endoplasmic reticulum

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A patient is diagnosed with an abnormality of oligopeptide disposal.

Which intracellular organelle is associated with the metabolism of oligopeptides?

(Please select 1 option)

○	Golgi apparatus
○	Lysosomes ← This is the correct answer
◉	Peroxisomes ✕ Incorrect answer selected
○	Ribosomes
○	Smooth endoplasmic reticulum

Lysosomes (lysis- breakage, soma- body), carry hydrolases that degrade

- Nucleotides
- Proteins
- Lipids
- Phospholipids.

They also remove carbohydrate, sulfate, or phosphate groups from molecules.

Ribosomes are intimately associated with the rough endoplasmic reticulum and are responsible for protein translation.

Peroxisomes are responsible for the metabolism of fatty acids within cells.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 14 mins 50 secs

Question: 22 of 33

A patient is found to have an acquired syndrome associated with defective breakdown and disposal of intracellular fatty acids.

Which intracellular organelle is concerned with the breakdown of fatty acids?

(Please select 1 option)

○	Golgi appartus
○	Lysosomes
○	Mitochondria
◉	Peroxisomes ✓ Correct
○	Smooth endoplasmic reticulum

Mitochondria are concerned with aerobic cell respiration and Golgi bodies are likely to be responsible for transporting products synthesised in the smooth endoplasmic reticulum.

Smooth endoplasmic reticulum is a site of lipid synthesis within the cell.

Lysosomes (lysis- breakage, soma- body) contain digestive enzymes which break down expendable cell organelles, engulfed viruses and other intracellular detritus.

Peroxisomes are responsible for the metabolism of fatty acids within cells.

Work Smart Session - MRCP Part 1

Question: 23 of 33

A 16-year-old girl presented with fever, headache and photophobia.

Investigations revealed:

Cerebrospinal fluid examination

Opening pressure	260 mm H_20	(50-180)
Total protein	0.8 g/l	(0.15-0.45)
Glucose	4.2 mmol/l	(3.3-4.4)
White cell count	60 per ml	(<5)
Lymphocytes	90%	(60-70)
Plasma glucose	6.4 mmol/l	(3.0-6.0)

What is the most likely diagnosis?

(Please select 1 option)

- Bacterial meningitis
- Cryptococcal meningitis
- Tuberculosis meningitis
- Viral encephalitis
- Viral meningitis

Submit answer | Skip question | Tag Question | Remove question

Lymphocytes	90%	(60-70)
Plasma glucose	6.4 mmol/l	(3.0-6.0)

What is the most likely diagnosis?

(Please select 1 option)

- ○ Bacterial meningitis
- ○ Cryptococcal meningitis
- ○ Tuberculosis meningitis
- ○ Viral encephalitis
- ◉ Viral meningitis ✓ Correct

A normal cerbrospinal fluid (CSF) glucose together with

- A CSF lymphocytosis
- An increased opening pressure, and
- A raised CSF protein

are typical of a viral meningitis, which would be high on the list of differentials in patients of this age group (together with bacterial meningitis).

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 18 mins 38 secs

Question: 24 of 33

A 17-year-old girl underwent emergency splenectomy after a domestic accident.

Which one of the following organisms is most likely to cause life-threatening infection in the future?

(Please select 1 option)

○	Actinomycosis
○	*Haemophilus influenzae*
○	*Pseudomonas aeruginosa*
○	*Staphylococcus aureus*
◉	*Streptococcus pneumoniae* ✓ Correct

Following splenectomy a person is at risk of *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, *Escherichia coli* and *Pseudomonas aeruginosa*.

By far the most common is *Streptococcus pneumoniae,* which can cause life-threatening infection.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 18 mins 38 secs

Question: 25 of 33

A 45-year-old man presents with an ulcer on his right foot.

He has a twenty year history of type 1 diabetes and currently uses mixed insulin twice daily.

On examination he has a small ulcer of approximately 2 cm diameter on the outer aspect of his right big toe.

His peripheral pulses are all palpable but he has a peripheral neuropathy to the mid shins.

The ulcer has an erythematous margin and is covered by pus.

What is the most likely infective organism?

(Please select 1 option)

- ○ *Escherichia coli*
- ○ MRSA
- ○ *Pseudomonas aeruginosa*
- ○ *Staphylococcus aureus*
- ○ *Streptococcus pyogenes*

Submit answer | Skip question | Tag Question | Remove question

He has a twenty year history of type 1 diabetes and currently uses mixed insulin twice daily.

On examination he has a small ulcer of approximately 2 cm diameter on the outer aspect of his right big toe.

His peripheral pulses are all palpable but he has a peripheral neuropathy to the mid shins.

The ulcer has an erythematous margin and is covered by pus.

What is the most likely infective organism?

(Please select 1 option)

○	*Escherichia coli*
○	MRSA
○	*Pseudomonas aeruginosa*
◉	*Staphylococcus aureus* ✓ Correct
○	*Streptococcus pyogenes*

Although infection in diabetic foot ulcers is usually mixed, the most likely infective organism in this case is *Staph. aureus*.

Methicillin-resistant *Staphylococcus aureus* (MRSA) would be less likely but might be suspected if the patient developed an infection in hospital or had recurrent admissions.

The most appropriate antibiotic therapy is flucloxacillin, plus another broad spectrum agent with advice that the patient should not weight bear and should wear appropriate footwear.

Work Smart Session - MRCP Part 1

Question: 26 of 33

A 50-year-old female presents with dyspnoea, a new murmur and fever and is diagnosed with infective endocarditis.

Which of the following is associated with the best prognosis?

(Please select 1 option)

○	Aortic valve infection
○	Culture negative endocarditis
○	Low complement levels
○	*Staphylococcus aureus* infection
◉	*Streptococcus viridans* infection ✓ Correct

Features suggestive of a worse prognosis are:

- Acute endocarditis (*Staphylococcus aureus*)
- Heart failure
- Intravenous drug abuse (often left and right sided disease)
- Prosthetic valve infection
- Infection of the aortic rather than mitral valve
- Associated rhythm disturbance.

Subacute bacterial endocarditis (*Streptococcus viridans*) has a better prognosis.

(Please select 1 option)

○	Candida
○	*Coxiella burnetii*
○	*Staphylococcus aureus*
◉	*Staphylococcus epidermidis* ✓ Correct
○	*Streptococcus viridans*

Prosthetic valve endocarditis arising within two months of valve surgery is generally the result of intraoperative contamination of the prosthesis or a bacteraemia postoperative complication.

The nosocomial nature of these infections is reflected in their primary microbial causes:

- Coagulase-negative staphylococci (*Staphylococcus epidermidis*)
- *S. aureus*
- Facultative Gram-negative bacilli
- Diphtheroids
- Fungi.

The oral cavity, skin, and upper respiratory tract are the respective primary portals for the viridans streptococci, staphylococci, and HACEK organisms (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella*, and *Kingella*), causing community-acquired native valve endocarditis.

Streptococcus bovis originates from the gastrointestinal tract, where it is associated with polyps and colonic tumours, and enterococci enter the bloodstream from the genitourinary tract.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 22 mins 14 secs

Question: 28 of 33

A woman had lunch at a Chinese restaurant.

In the evening she presented with diarrhoea and vomiting. There was no fever.

Which of the following is the likely cause of food poisoning in her case?

(Please select 1 option)

- *Bacillus cereus*
- *Clostridium perfringens*
- *Escherichia coli*
- *Staphylococcus aureus*
- *Yersinia enterocolitica*

Submit answer | Skip question | Tag Question | Remove question

In the evening she presented with diarrhoea and vomiting. There was no fever.

Which of the following is the likely cause of food poisoning in her case?

(Please select 1 option)

◉	*Bacillus cereus* ✓ Correct
○	*Clostridium perfringens*
○	*Escherichia coli*
○	*Staphylococcus aureus*
○	*Yersinia enterocolitica*

Bacillus cereus food poisoning is the general description although two recognised types of illness are caused by two distinct metabolites. The diarrhoeal type of illness is caused by a large molecular weight protein, while the vomiting (emetic) type of illness is believed to be caused by a low molecular weight, heat-stable peptide.

The onset of watery diarrhoea, abdominal cramps, and pain occurs 6-15 hours after consumption of contaminated food. Symptoms usually persist for 24 hours. The emetic type of food poisoning is characterised by nausea and vomiting within 0.5 to 6 hours after consumption of contaminated foods. Occasionally, abdominal cramps and/or diarrhoea may also occur. Duration of symptoms is generally less than 24 hours.

A wide variety of foods including meats, milk, vegetables, and fish have been associated with the diarrhoeal type food poisoning. The vomiting-type outbreaks have generally been associated with rice products. *Staphylococcus aureus* and *Clostridium perfringens* are associated with meat and *Yersinia enterocolitica* with milk

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 24 mins 19 secs

Question: 29 of 33

A group of construction workers presented to the emergency department with diarrhoea, flushing, sweating and a hot mouth. They fell ill minutes after eating lunch in the staff canteen. They admitted that they had eaten tuna fish and wine.

What is the likely cause of food poisoning?

(Please select 1 option)

○	*Clostridium perfringens*
○	Heavy metal
○	Mushroom
○	Scrombotoxin
○	*Staphylococcus aureus*

Question: 29 of 33

A group of construction workers presented to the emergency department with diarrhoea, flushing, sweating and a hot mouth. They fell ill minutes after eating lunch in the staff canteen. They admitted that they had eaten tuna fish and wine.

What is the likely cause of food poisoning?

(Please select 1 option)

○	*Clostridium perfringens*
○	Heavy metal
○	Mushroom
○	Scrombotoxin ← This is the correct answer
◉	*Staphylococcus aureus* ✕ Incorrect answer selected

Scrombotoxin food poisoning is caused by the ingestion of foods that contain high levels of histamine and possibly other vasoactive amines and compounds.

Histamine and other amines are formed by the growth of certain bacteria and the subsequent action of their decarboxylase enzymes on histidine and other amino acids in food, either during the production of a product such as Swiss cheese or by spoilage of foods such as fishery products, particularly tuna or mahi mahi.

Incubation period is 10-60 minutes.

Work Smart Session - MRCP Part 1

Time taken: 4 mins 52 secs

Question: 2 of 33

A 43-year-old Pakastani female presents with a two month history of weight loss, fever and night sweats.

Chest x ray reveals a large right sided pleural effusion.

What investigation is most likely to confirm a diagnosis of suspected TB?

(Please select 1 option)

○	**A** CT scan of thorax
○	**B** Interferon gamma releasing assay (IGRA)
○	**C** Pleural aspirate
◉	**D** Pleural biopsy ✓ Correct
○	**E** Sputum analysis

For suspected pleural TB, pleural biopsy sent in normal saline for AFB smear, mycobacterial culture and histology is the most sensitive method for laboratory confirmation.

In cases of suspected TB, every effort should be made to confirm a suspected diagnosis by culture. Susceptibility testing is important as detection of resistance alters the combination of drugs and duration of treatment.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 26 mins 18 secs

Question: 30 of 33

A 41-year-old male has been diagnosed with infective endocarditis.

Which of the following is associated with the best prognosis?

(Please select 1 option)

- Aortic valve infection
- Intravenous drug abuse
- Prosthetic valve infection
- *Staphylococcus aureus* infection
- *Streptococcus viridans* infection

Submit answer | Skip question | Tag Question | Remove question

Question: 30 of 33

A 41-year-old male has been diagnosed with infective endocarditis.

Which of the following is associated with the best prognosis?

(Please select 1 option)

○	Aortic valve infection
○	Intravenous drug abuse
○	Prosthetic valve infection
○	*Staphylococcus aureus* infection
◉	*Streptococcus viridans* infection ✓ Correct

Features suggestive of a worse prognosis are

- Acute endocarditis (*Staphylococcus aureus*)
- Heart failure
- IV drug abuse (often left and right sided disease)
- Prosthetic valve infection
- Infection of the aortic rather than mitral valve
- Associated rhythm disturbance.

Subacute bacterial endocarditis (*Streptococcus viridans*) has a better prognosis.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 26 mins 46 secs

Question: 31 of 33

Seventeen of twenty-four passengers on a Nile cruise develop bloody diarrhoea on the third day.

Which of the following organisms is the likely cause?

(Please select 1 option)

- *Entamoeba histolytica*
- *Giardia lamblia*
- *Schistosoma mansonii*
- *Shigella dysenteriae*
- *Vibrio cholerae*

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 27 mins 17 secs

Question: 31 of 33

Seventeen of twenty-four passengers on a Nile cruise develop bloody diarrhoea on the third day.

Which of the following organisms is the likely cause?

(Please select 1 option)

◉	*Entamoeba histolytica* ✕ Incorrect answer selected
○	*Giardia lamblia*
○	*Schistosoma mansonii*
○	*Shigella dysenteriae* ← This is the correct answer
○	*Vibrio cholerae*

Dysentery is characterised by the passing of frequent (sometimes very frequent) stools, that may contain blood, mucus or pus.

Shigella dysenteriae is responsible for bacillary dysentery, a disease most often associated with crowded, unsanitary conditions. Other species of *Shigella* may produce milder forms of diarrhoeal disease.

Dysentery is an oral infection transmitted via faecal contamination of water or food. During the one to four day incubation period, penetration of bacteria into the mucosal epithelial cells of the intestine causes an intense irritation of the intestinal wall, producing cramps and a watery, bloody diarrhoea.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 27 mins 17 secs

Question: 32 of 33

A 33-year-old male with type 1 diabetes presents with a two day history of pain, swelling and redness in his left middle finger. This began after he pricked his finger in the garden whilst pruning a bush.

His diabetic control has been quite reasonable with a HbA1c of 7.1% (3.8-6.4) on basal bolus insulin consisting of lispro tds and Humulin I in the evenings.

On examination he has a painful, red and swollen middle finger with the redness extending to the metacarpophalangeal joint. He is diagnosed with cellulitis.

What is the most appropriate treatment for this patient?

(Please select 1 option)

- Admit to hospital for IV antibiotics
- Oral flucloxacillin only
- Oral metronidazole only
- Oral penicillin V only
- Oral penicillin V and flucloxacillin

Submit answer | Skip question | Tag Question | Remove question

A 33-year-old male with type 1 diabetes presents with a two day history of pain, swelling and redness in his left middle finger. This began after he pricked his finger in the garden whilst pruning a bush.

His diabetic control has been quite reasonable with a HbA1c of 7.1% (3.8-6.4) on basal bolus insulin consisting of lispro tds and Humulin I in the evenings.

On examination he has a painful, red and swollen middle finger with the redness extending to the metacarpophalangeal joint. He is diagnosed with cellulitis.

What is the most appropriate treatment for this patient?

(Please select 1 option)

○	Admit to hospital for IV antibiotics
○	Oral flucloxacillin only
○	Oral metronidazole only
○	Oral penicillin V only
◉	Oral penicillin V and flucloxacillin ✓ Correct

The patient has digital cellulitis and the most likely organisms responsible are *Strep. pyogenes* or *Staph. aureus*.

The most appropriate treatment is penicillin V and flucloxacillin which should result in a rapid improvement.

If there is a deterioration then admission for IV antibiotics may be required but this should be unnecessary with appropriate antibiotic selection.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 30 mins 56 secs

Question: 33 of 33

A 16-year-old boy presented with fever, headache and neck stiffness for 24 hours. He had an identical illness requiring admission to hospital for one year previously.

Cerebrospinal fluid analysis shows white cells of 400/ml with a 90% neutrophilia and gram stain revealed scanty gram-negative diplococci.

Which component of the immune system is likely to be defective?

(Please select 1 option)

- B lymphocytes
- Complement pathway
- Immunoglobulin
- Neutrophils
- T lymphocytes

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 33 mins 4 secs

Question: 33 of 33

A 16-year-old boy presented with fever, headache and neck stiffness for 24 hours. He had an identical illness requiring admission to hospital for one year previously.

Cerebrospinal fluid analysis shows white cells of 400/ml with a 90% neutrophilia and gram stain revealed scanty gram-negative diplococci.

Which component of the immune system is likely to be defective?

(Please select 1 option)

○	B lymphocytes
◉	Complement pathway ✓ Correct
○	Immunoglobulin
○	Neutrophils
○	T lymphocytes

This young man has a recurrent meningococcal meningitis, and deficiencies of complement C5-9 predispose to *Neisseria* infections (complement deficiencies).

One must recognise that the diplococci seen on microscopy are those of *Neisseria meningitides*.

Work Smart Session - MRCP Part 1

Time taken: 6 mins 21 secs

Question: 3 of 33

A 27-year-old Somali female presents with a two month history of weight loss, fever and night sweats.

Chest x ray reveals right upper lobe infiltrates. 3 x sputa are AFB smear.

What is the next most appropriate investigation?

(Please select 1 option)

○	**A** Bronchoalveolar lavage (BAL) ← This is the correct answer
○	**B** CT scan of chest
○	**C** HIV test
◉	**D** HIV test ✕ Incorrect answer selected
○	**E** Tuberculin skin test (TST)

The history, clinical presentation and radiological findings are highly suggestive of pulmonary TB.

BAL is more sensitive than sputum collection at detecting TB, either by smear or culture.

In cases of suspected TB every effort should be made to confirm a suspected diagnosis by culture. Susceptibility testing is important as detection of resistance alters the combination of drugs and duration of treatment.

Work Smart Session - MRCP Part 1

Time taken: 7 mins 50 secs

Question: 4 of 33

A 20-month-old baby is brought to the emergency department with a two day history of irritability, fever and non-blanching rash. BP was normal.

What is the likeliest diagnosis?

(Please select 1 option)

○	**A** *H. influenzae*
○	**B** *L. monocytogenes*
◉	**C** *N. meningitidis* ✓ Correct
○	**D** *S. aureus*
○	**E** *Streptococcus pneumoniae*

Meningococcal disease is an important cause of severe infection in young infants. Early recognition and treatment is essential for a favourable outcome.

Although other organisms can cause meningitis, *N. meningitidis* is the likeliest cause.

At 20 months, the infant should have been immunised against *H. influenzae* serotype B.

Work Smart Session - MRCP Part 1

Time taken: 8 mins 55 secs

Question: 5 of 33

A sexually active female presents to a GU clinic with multiple painful genital ulcers.

What is the likeliest cause?

(Please select 1 option)

○	**A** *Chlamydia trachomatis*
○	**B** Herpes simplex ← This is the correct answer
○	**C** *Haemophilus ducreyi*
○	**D** Primary HIV infection
◉	**E** *Treponema pallidum* ✕ Incorrect answer selected

Herpes simplex is a sexually transmitted disease and the commonest cause of multiple painful genital lesions.

C. trachomatis, *H. ducreyi* and *T. pallidum* do not normally cause painful genital ulceration.

Compared to herpes simplex, primary human immunodeficiency virus (HIV) infection is an unusual cause of genital ulceration.

Work Smart Session - MRCP Part 1

Time taken: 8 mins 55 secs

Question: 6 of 33

A 72-year-old female presents with a two month history of poor appetite, lethargy, intermittent fever and night sweats. She has poor dentition and over the last 12 months has required dental extraction.

On examination, a murmur consistent with mitral regurgitation is heard. A transthoracic echocardiogram reveals a vegetation on the mitral valve.

What is the likeliest cause of her endocarditis?

(Please select 1 option)

○	**A** *C. burnetii*
○	**B** *E. faecalis*
○	**C** MRSA
○	**D** *S. aureus*
○	**E** *S. mutans*

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 13 mins 18 secs

Question: 6 of 33

A 72-year-old female presents with a two month history of poor appetite, lethargy, intermittent fever and night sweats. She has poor dentition and over the last 12 months has required dental extraction.

On examination, a murmur consistent with mitral regurgitation is heard. A transthoracic echocardiogram reveals a vegetation on the mitral valve.

What is the likeliest cause of her endocarditis?

(Please select 1 option)

○	**A** *C. burnetii*
○	**B** *E. faecalis*
○	**C** MRSA
◉	**D** *S. aureus* ✕ Incorrect answer selected
○	**E** *S. mutans* ← This is the correct answer

S. mutans is a member of the viridans *Streptococcus* group and a common cause of bacterial endocarditis.

Poor dentition and procedures such as dental extraction are associated with transient viridans streptococcal bacteraemia.

In the presence of a pre-existing cardiac lesion this may have caused infective endocarditis.

Work Smart Session - MRCP Part 1

Time taken: 14 mins 42 secs

Question: 7 of 33

A 72-year-old male presents with a two month history of poor appetite, lethargy, intermittent fever and night sweats. Four months previously he had undergone TURP for benign prostatic hypertrophy.

On examination a murmur consistent with mitral regurgitation is heard. A transthoracic echocardiogram reveals a vegetation on the mitral valve.

What is the likeliest cause of his endocarditis?

(Please select 1 option)

○	**A** *C. burnetii*
○	**B** *E. faecalis* ← This is the correct answer
○	**C** MRSA
○	**D** *S. aureus*
◉	**E** *S. mutans* ✕ Incorrect answer selected

E. faecalis is a common cause of bacterial endocarditis following a urological procedure.

Urological procedures, such astransurethral resection of the prostate (TURP), may cause a transient *E. faecalis* bacteraemia.

In the presence of a pre-existing cardiac lesion this may have caused infective endocarditis.

Work Smart Session - MRCP Part 1

Time taken: 15 mins 53 secs

Question: 8 of 33

A 25-year-old female recently returned from Nigeria, presents to the emergency department with a two day history of fever and rigors.

Subsequently she develops a seizure.

What is the next most appropriate immediate investigation?

(Please select 1 option)

○	**A** Blood culture
◉	**B** Blood film for malarial parasites ✓ Correct
○	**C** CT scan of head
○	**D** Lumbar puncture
○	**E** MR scan of head

With a recent history of travel to Nigeria, cerebral malaria caused by *P. falciparum* should be considered as a likely cause of her symptoms.

Therefore, a malaria blood film should be performed.

Other investigations may be required but investigations for malaria should be performed immediately.

Work Smart Session - MRCP Part 1

Time taken: 26 mins 2 secs

Question: 9 of 33

A 25-year-old male presents with fever malaise and lethargy two weeks after visiting family in India.

A blood film for malaria parasites is reported as negative.

What is the next most appropriate investigation?

(Please select 1 option)

◉	**A** Blood culture ✓ Correct
○	**B** Chest x ray
○	**C** Interferon gamma releasing assay (IGRA)
○	**D** Urine culture
○	**E** Widal test

After malaria, enteric fevers are important to exclude.

Blood cultures are the most important investigation for enteric fevers caused by *Salmonella typhi* or *S. paratyphi*.

The Widal test, a demonstration of agglutinating antibodies against somatic O and flagella H antigen of *Salmonella* species is non-specific and, therefore, less reliable.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 72-year-old man comes to the surgery with his wife.

She has witnessed two seizures at home, both of which have lasted for no longer than two minutes or so, accompanied by generalised limb jerking and incontinence of urine. He has been very embarrassed about the problem and did not want to come for review. She did not call an ambulance at the time as he seemed to be comfortable afterwards and she did not want the staff to see him "in a mess".

He has a history of cerebrovascular disease having suffered a minor stroke one year earlier, and suffered a myocardial infarction some three years ago. Medication includes ramipril, amlodipine, atorvastatin and aspirin.

On examination in the surgery he looks well. His BP is 142/79 mmHg, his pulse 75 and regular. Neurological examination is unremarkable apart from some very minor loss of co-ordination affecting his left hand. He wants you to arrange some investigations before bothering the hospital doctors.

Investigations show

Haemoglobin	12.1 g/dl	(13.5-18)
White cell count	8.2 x 10^9/l	(4-10)
Platelets	301 x 10^9/l	(150-400)
Sodium	141 mmol/l	(134-143)
Potassium	5.1 mmol/l	(3.5-5)
Creatinine	149 µ/l	(60-120)
ESR	12	(<20)
ECG	Sinus rhythm Inferior Q waves	

Which one of the following initial steps would be most appropriate in this case?

(Please select 1 option)

- ○ Carotid ultrasound scanning
- ○ EEG
- ○ Start low dose carbamazepine
- ○ Start low dose sodium valproate
- ○ Tilt table test

Work Smart Session - MRCP Part 1

Time taken: 28 mins 20 secs

Question: 10 of 66

A 23-year-old female attends clinic for a routine appointment regarding a six month history of occasional fits.

She has seen the neurologists who have diagnosed idiopathic epilepsy and have prescribed lamotrigine. She informs you that she is doing well with this medication and has not had a fit for two months.

She has been told that she must stop driving but you have seen that she drove to attend the clinic. You discuss this with her and insist that she stops driving to which she informs you that she had stopped driving but since she is fit free she must continue to drive because of her employment.

Which of the following is the most appropriate action to take in these circumstances?

(Please select 1 option)

○	Inform patient that you will notify the DVLA
○	Inform patient that you will notify the police
○	Inform the epilepsy clinic that she is still driving and allow them to deal with this issue.
○	You cannot inform any external body due to patient confidentiality.
○	Your only action is to write in the notes that the patient has been repeatedly warned but chose to ignore advice as she presents no serious risk in view of her epilepsy control.

◉	Inform patient that you will notify the DVLA ✓ Correct
○	Inform patient that you will notify the police
○	Inform the epilepsy clinic that she is still driving and allow them to deal with this issue.
○	You cannot inform any external body due to patient confidentiality.
○	Your only action is to write in the notes that the patient has been repeatedly warned but chose to ignore advice as she presents no serious risk in view of her epilepsy control.

The law is quite clear on such issues regarding epilepsy and the ability to drive. If the diagnosis is confirmed the patient must stop driving and inform the DVLA regarding the diagnosis.

If the patient continues to drive despite advice to the contrary then the doctor has a duty of care to society overriding confidentiality to the patient and may inform the DVLA.

Work Smart Session - MRCP Part 1

Time taken: 30 mins 34 secs

Question: 11 of 66

A 52-year-old female asks you for copies of her medical records. Within the records are several letters from hospital specialists, one of which refers to the patient in very unflattering terms. There is also a note in the records of a call that was made to the surgery by a neighbour of the patient who reported hearing noises through the wall and expressed concern that the patient may be suffering domestic violence.

Are the following statements true?

(Please select 1 option)

- Under the Data Protection Act 1998 you are allowed to withhold the note of the telephone call from the neighbour.
- Under the Data Protection Act 1998 you are obliged to disclose the record in its entirety
- You may withhold access to any references to third parties, including hospital specialists.
- You must seek the consent of the hospital specialists before disclosing their letters
- You must withhold access to any references to third parties, including hospital specialists

(Please select 1 option)

○	Under the Data Protection Act 1998 you are allowed to withhold the note of the telephone call from the neighbour. ← This is the correct answer
○	Under the Data Protection Act 1998 you are obliged to disclose the record in its entirety
○	You may withhold access to any references to third parties, including hospital specialists.
◉	You must seek the consent of the hospital specialists before disclosing their letters ✕ Incorrect answer selected
○	You must withhold access to any references to third parties, including hospital specialists

Under data protection etc. The legislative framework for the disclosure of medical records is the Data Protection Act 1998. Under the Act, you may withhold access to any part of the record if you consider that disclosure would cause serious mental or physical harm to the patient or another person. You may also withhold access to part of the record that in effect discloses information about an identifiable third party, unless you have the consent of the third party to make the disclosure or it is reasonable in all the circumstances to make the disclosure without seeking consent. Information in a health record made by a healthcare professional involved in the care of the patient does not count as third party information for this purpose; where, as in this case, disclosure of a hospital letter is likely to generate a complaint, you may choose to inform the author that the disclosure has been made but are not obliged to do so. If information is likely to cause serious harm to the physical or mental health or condition of the data subject or any other person, then it can be withheld regardless of the author.

Question: 12 of 66

A 56-year-old male with severe brain damage is apnoeic, unsedated, and temperature 36.9°C.

He is intubated and ventilated. His biochemistry is normal.

The combination of which of the following specialists would be able to confirm brain stem death?

(Please select 1 option)

○	Consultant/Associate specialist with three years experience
○	Consultant/Specialist registrar of two years experience
○	Staff grade with five years experience/ Consultant
○	Senior house officer of two years experience/Specialist registrar of five years experience
○	Specialist registrar with five years experience/Specialist registrar with five years experience

Time taken: 34 mins 19 secs

Question: 12 of 66

A 56-year-old male with severe brain damage is apnoeic, unsedated, and temperature 36.9°C.

He is intubated and ventilated. His biochemistry is normal.

The combination of which of the following specialists would be able to confirm brain stem death?

(Please select 1 option)

◉	Consultant/Associate specialist with three years experience ✗ Incorrect answer selected
○	Consultant/Specialist registrar of two years experience
○	Staff grade with five years experience/ Consultant ← This is the correct answer
○	Senior house officer of two years experience/Specialist registrar of five years experience
○	Specialist registrar with five years experience/Specialist registrar with five years experience

Criteria for the confirmation of brain stem death have to be tested by a consultant and confirmed by a doctor of at least five years post- registration who has experience in the testing of brain stem death.

Work Smart Session - MRCP Part 1

Time taken: 34 mins 19 secs

Question: 13 of 66

An 82-year-old lady with dementia presents from a nursing home with vaginal discharge.

High vaginal swabs have confirmed gonorrheal infection and she has been commenced on appropriate treatment.

What else would you like to do for this patient?

(Please select 1 option)

○	Contact tracing
○	Inform family
○	Inform police
○	None of the above
○	Non-official enquiry

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

What else would you like to do for this patient?

(Please select 1 option)

○	Contact tracing
◉	Inform family ✓ Correct
○	Inform police
○	None of the above
○	Non-official enquiry

This appears to be a case of elder sexual abuse.

For those who are legally competent voluntary referrals to social services, victims' services, the criminal justice system, or any other appropriate resource agency are encouraged.

Doctors should not report the incidence without the patient's permission.

Here this demented lady is not legally competent. In this case one should discuss this case with the next of kin first to establish if there truly is sexual abuse or whether in fact this patient has been having a relationship with a third party.

The facts should be established first before involving the police.

If in any doubt, contact your medical defence organisation.

Work Smart Session - MRCP Part 1

Time taken: 35 mins 5 secs

Question: 14 of 66

A 78-year-old male dies and is found by his children the following morning (after having seen him alive the night before). His GP attends to certify him dead.

The patient had a known history of ischaemic heart disease and was treated in the local hospital where angiography performed nine months previously for angina had revealed some insignificant coronary artery disease of two vessels for which medical therapy was deemed most appropriate. He had also been diagnosed eight years previously with diabetes mellitus for which he took metformin and gliclazide.

He had seen the practice nurse two weeks ago for review of his diabetes. One month ago he had seen the diabetologists for his annual review and had seen the cardiologists approximately six months ago. He had last seen a partner in the practice six weeks ago for advice concerning driving licence registration.

The family are keen to have a death certificate issued and proceed to cremation. They do not want any post mortem examination.

Which of the following is true concerning the issuing of a death certificate?

(Please select 1 option)

○	The certifying doctor may issue a death certificate
○	The death needs to be referred to the coroner
○	The diabetologist can certify the death.
○	The partner in the practice may issue a death certificate
○	The practice nurse can certify the death

weeks ago for advice concerning driving licence registration.

The family are keen to have a death certificate issued and proceed to cremation. They do not want any post mortem examination.

Which of the following is true concerning the issuing of a death certificate?

(Please select 1 option)

○	The certifying doctor may issue a death certificate
◉	The death needs to be referred to the coroner ✓ Correct
○	The diabetologist can certify the death.
○	The partner in the practice may issue a death certificate
○	The practice nurse can certify the death

Death certification is becoming a hot area post Shipman.

A death certificate may be completed if the practitioner has seen the deceased within 14 days of the death (28 days in NI). In this case the patient had been seen six weeks previously by the partner.

Consequently and in view of the sudden death the coroner should be informed although he may decide that in the circumstances reported the doctor may be able to issue a death certificate stating ischaemic heart disease if he deems appropriate and on the balance of advice given to him.

Work Smart Session - MRCP Part 1

Time taken: 37 mins 54 secs

Question: 15 of 66

Which one of the following deaths should be reported to the coroner?

(Please select 1 option)

○	A 73-year-old female who had undergone a hip replacement two months previously presents with severe chest pain and breathlessness. She is diagnosed with pulmonary embolism but dies.
○	A 72-year-old male is admitted with a myocardial infarction and dies 48 hours following admission.
○	A 69-year-old male with pneumoconiosis is admitted with fever and breathlessness. He dies two days later from pneumonia.
○	A 62-year-old male with a two year history of severe dementia is admitted from a nursing home with fever and breathlessness. He dies three days later with pneumonia.
○	A 52-year-old male with a long history of alcohol abuse is admitted with confusion. He dies two days later with hepatic failure.

She is diagnosed with pulmonary embolism but dies.

A 72-year-old male is admitted with a myocardial infarction and dies 48 hours following admission.

A 69-year-old male with pneumoconiosis is admitted with fever and breathlessness. He dies two days later from pneumonia. ← This is the correct answer

A 62-year-old male with a two year history of severe dementia is admitted from a nursing home with fever and breathlessness. He dies three days later with pneumonia. ✗ Incorrect answer selected

A 52-year-old male with a long history of alcohol abuse is admitted with confusion. He dies two days later with hepatic failure.

Increasingly emphasis is placed on the appropriate reporting of deaths particularly from the enquiries into Shipman and the Coroners' Reform Bill. In fact, it is the duty of the Registrar of Births, Deaths and Marriages to report a death to the coroner but doctors need to be aware of the circumstances in which a death should be reported.

These include:

- The cause of death is unknown
- The deceased was not seen by the certifying doctor either after death or within 14 days before death
- The death was violent or unnatural
- The death may be due to an accident
- The death may be due to self neglect or neglect by others
- The death may be the result of industrial illness or due to the person's employment (as in D pneumoconiosis being an industrial disease)
- The death may be due to an abortion
- The death occurred during an operation or before recovery from anaesthesia
- The death may be suicide
- The death occurred during or shortly after being taken into police custody.

The MDU have published a guide to Coroners Inquiries which is free to members:

Work Smart Session - MRCP Part 1

Time taken: 39 mins 51 secs

Question: 16 of 66

A 54-year-old male who is a HGV driver and has a 10 year history of type 2 diabetes is seen on annual review.

His glycaemic control is poor with a HBA1c of 10.5% on maximal oral hypoglycaemic therapy (3.8-6.4).

You suggest switching to insulin but he refuses to do this as he would lose his HGV licence. He also refuses to inform the DVLA himself.

What is the most appropriate action in this case?

(Please select 1 option)

- Continue to review patient in clinic and accept that he continues to drive
- Discharge him from clinic as there is nothing more that you can do
- Inform his employer that he must stop driving and suggest administrative work
- Inform the DVLA even if the patient withholds his consent
- Tell his next of kin that they should inform the DVLA that he is nol onger fit to drive

His glycaemic control is poor with a HBA1c of 10.5% on maximal oral hypoglycaemic therapy (3.8-6.4).

You suggest switching to insulin but he refuses to do this as he would lose his HGV licence. He also refuses to inform the DVLA himself.

What is the most appropriate action in this case?

(Please select 1 option)

◉	Continue to review patient in clinic and accept that he continues to drive ✓ Correct
○	Discharge him from clinic as there is nothing more that you can do
○	Inform his employer that he must stop driving and suggest administrative work
○	Inform the DVLA even if the patient withholds his consent
○	Tell his next of kin that they should inform the DVLA that he is nol onger fit to drive

In this particular case, the patient has poor glycaemic control, but otherwise has no features whatsoever that preclude him from driving such as retinopathy, neuropathy or hypoglycaemic episodes.

You cannot therefore force this patient to switch to insulin and neither can you stop him driving.

He will continue to need a regular medical every three years for his continued HGV licence.

Work Smart Session - MRCP Part 1

Time taken: 43 mins 24 secs

Question: 17 of 66

A 22-year-old female is admitted following severe injuries sustained in a road traffic accident. She is communicative but in shock with low blood pressure and tachycardia.

You realise that without a transfusion she will die but she informs you that she has recently become a Jehovah's Witness and that she adamantly refuses transfusion, despite knowledge that she could die.

Her distraught parents tell you that she has only recently joined the Jehovah's Witnesses and implore you to transfuse her, as they insist that she does not know her own mind.

Together with other intervention which she permits, what is the most appropriate action regarding possible transfusion?

(Please select 1 option)

- Declare her incompetent and transfuse
- Do not transfuse even if it means that she will die
- Get immediate psychiatric intervention to section her and then transfuse
- Transfuse immediately, irrespective of the patient's wishes
- Wait until she becomes unconscious and then get consent from her parents to transfuse

shock with low blood pressure and tachycardia.

You realise that without a transfusion she will die but she informs you that she has recently become a Jehovah's Witness and that she adamantly refuses transfusion, despite knowledge that she could die.

Her distraught parents tell you that she has only recently joined the Jehovah's Witnesses and implore you to transfuse her, as they insist that she does not know her own mind.

Together with other intervention which she permits, what is the most appropriate action regarding possible transfusion?

(Please select 1 option)

○	Declare her incompetent and transfuse
○	Do not transfuse even if it means that she will die ← This is the correct answer
○	Get immediate psychiatric intervention to section her and then transfuse
○	Transfuse immediately, irrespective of the patient's wishes
◉	Wait until she becomes unconscious and then get consent from her parents to transfuse ✕ Incorrect answer selected

The patient appears competent and has elected to refuse the transfusion. Despite the parents' protestation you must respect the patient's wishes if, as seems likely here, she is making a reasoned judgement.

If the patient refuses the transfusion then even if she slips into unconsciousness you are not permitted to treat with transfusion even if it is in her best interests.

Work Smart Session - MRCP Part 1

Time taken: 45 mins 25 secs

Question: 18 of 66

A 30-year-old male is unconscious on admission following a road traffic accident. He was the driver of the car and there is the suspicion that he was responsible for the accident in which a passenger of another car died. In attendance with the patient is his wife who was uninjured in the accident.

The police are keen to obtain a blood sample for alcohol measurement but the patient is incapable of giving consent for this procedure.

What is the most appropriate action in these circumstances?

(Please select 1 option)

○	Draw a blood sample for later analysis when the patient is competent to consent.
○	Draw a blood sample which can be analysed immediately.
○	Inform the police that you may only take blood samples on medical grounds.
○	Obtain consent from his wife, as next of kin, to draw the blood sample.
○	Refuse to obtain a blood sample until the patient is competent to provide consent.

Submit answer | Skip question | Tag Question | Remove question

his wife who was uninjured in the accident.

The police are keen to obtain a blood sample for alcohol measurement but the patient is incapable of giving consent for this procedure.

What is the most appropriate action in these circumstances?

(Please select 1 option)

○	Draw a blood sample for later analysis when the patient is competent to consent. ← This is the correct answer
◉	Draw a blood sample which can be analysed immediately. ✕ Incorrect answer selected
○	Inform the police that you may only take blood samples on medical grounds.
○	Obtain consent from his wife, as next of kin, to draw the blood sample.
○	Refuse to obtain a blood sample until the patient is competent to provide consent.

There is clear guidance published on such a situation by the BMA.

Following the Police Reform Act, it is no longer necessary to obtain consent from unconscious or incapacitated drivers.

However, the sample is not tested until the person regains competence and gives valid consent to it being tested.

A competent person who refuses to allow his or her sample to be tested might be liable to prosecution.

Similarly, the new law recognises the duty to justice.

Work Smart Session - MRCP Part 1

Time taken: 49 mins 11 secs

Question: 19 of 66

Which of the following has been shown to increase the risk of prostate cancer?

(Please select 1 option)

○	Caucasian race
◉	Exposure to cadmium ✓ Correct
○	Family history of colon cancer
○	Low intake of animal fats
○	Occupational exposure to dust

Black ethnicity is associated with a higher risk of prostate cancer than white.

A family history of breast cancer increases the risk of prostate cancer, as does a family history of prostate cancer.

An occupation in farming also seems to increase the risk of prostate cancer.

High intake of animal fats, and low selenium intake, as well as exposure to radiation and cadmium all increase the risk of prostate cancer.

Potassium	5.1 mmol/l	(3.5-5)
Creatinine	149 µ/l	(60-120)
ESR	12	(<20)
ECG	Sinus rhythm Inferior Q waves	

Which one of the following initial steps would be most appropriate in this case?

(Please select 1 option)

- ◉ Carotid ultrasound scanning ✓ Correct
- ○ EEG
- ○ Start low dose carbamazepine
- ○ Start low dose sodium valproate
- ○ Tilt table test

EEG measurement is less useful in an elderly population, most likely because of structural changes related to age and pre-existing cerebrovascular disease. MRI however may be useful in detecting any structural abnormality such as a tumour, local vascular abnormality or old cerebral infarct.

In patients with a history of previous stroke foci of epileptic activity can occur in the penumbra around the previous infarct. In view of his previous stroke, carotid ultrasound scanning is also an important part of the initial assessment.

Finally, bearing in mind his previous infarct, he should be considered for 72 hour ECG monitoring, to exclude the possibility of a significant cardiac arrhythmia.

Work Smart Session - MRCP Part 1

Time taken: 49 mins 11 secs

Question: 20 of 66

You intend to undertake a study of patients who have undergone excision of minor lumps and bumps over the last five years.

Specifically you wish to compare post-operative infection rates and also whether there are any differences between the clinical diagnosis and the histological diagnosis between the differing grades of practitioner performing the procedure.

Which of the following statements is correct concerning this study?

(Please select 1 option)

- Approval for the study must be obtained from the local ethics committee.
- If a study had already published with exactly the same concept then this constitutes plagiarism.
- If such a study has already been published then the investigators must obtain consent from the original authors to replicate their work.
- The study is flawed in its design and should not be performed.
- This is an audit and does not require ethical committee approval.

You intend to undertake a study of patients who have undergone excision of minor lumps and bumps over the last five years.

Specifically you wish to compare post-operative infection rates and also whether there are any differences between the clinical diagnosis and the histological diagnosis between the differing grades of practitioner performing the procedure.

Which of the following statements is correct concerning this study?

(Please select 1 option)

◉	Approval for the study must be obtained from the local ethics committee. ✓ Correct
○	If a study had already published with exactly the same concept then this constitutes plagiarism.
○	If such a study has already been published then the investigators must obtain consent from the original authors to replicate their work.
○	The study is flawed in its design and should not be performed.
○	This is an audit and does not require ethical committee approval.

This is not an audit.

There is no information provided to indicate that there are either any local or national guidelines relating to such a study. Furthermore there is no information provided to indicate that there is a specific clinical problem to which an audit should be addressed.

Consequently this is a research study and is a retrospective study. As such it requires local ethical committee approval.

The study itself seems very reasonable and even if it were published elsewhere it would still be reasonable to perform in the investigator's practice as the outcomes may be completely different.

Using the same methods as another study is perfecly justifiable, if only to prove the veracity of the original publication. No consent is required from the original authors if a similar study has already been published.

Work Smart Session - MRCP Part 1

Time taken: 54 mins 7 secs

Question: 21 of 66

You are intending to publish a case report as a fascinoma of the month within a national medical journal. As part of the publication you provide an image from the MRI film of the abdomen.

Medical illustration have transferred the film to electronic format and have removed all patient identification markings. The case report itself is otherwise completely anonymous.

Which of the following concerning consent is correct?

(Please select 1 option)

○	Consent for publication may not be required depending on the journal to which the manuscript is submitted
○	Consent for publication of the image must be obtained from the radiologist
○	Consent for publication must be sought from the local ethics committee
○	Patient consent for publication is not required
○	Patient consent must be provided for publication

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Medical illustration have transferred the film to electronic format and have removed all patient identification markings. The case report itself is otherwise completely anonymous.

Which of the following concerning consent is correct?

(Please select 1 option)

○	Consent for publication may not be required depending on the journal to which the manuscript is submitted
○	Consent for publication of the image must be obtained from the radiologist
○	Consent for publication must be sought from the local ethics committee
○	Patient consent for publication is not required
◉	Patient consent must be provided for publication ✓ Correct

There is much controversy concerning case reports and consent, but without question, prior to publication, and particularly as you are using images, consent for publication must be obtained from the patient for use of both images and for the publication of the case report. This consent must also be appropriately informed.

All UK journals expect this prior to publication despite the anonymity of the subject matter. This is not an issue for which medical ethics committees are involved.

This is a complex area and there is flexibility around publication of images. However, there have been incidences of x rays being published which have been deemed to have been an invasion of privacy.

Work Smart Session - MRCP Part 1

Time taken: 55 mins 59 secs

Question: 22 of 66

An 82-year-old female is reviewed after the staff of the nursing home in which she resides expressed concern regarding a vaginal discharge.

She has been in the nursing home for the last year and has profound Alzheimer's dementia.

Culture of the discharge reveals *Neisseria gonorrhoeae*.

Which is the most appropriate course of action for this patient?

(Please select 1 option)

- Contact the police
- Contact tracing of sexual partners
- Informal enquiry to the nursing home
- Seek advice from the MDU
- Treat the patient and discharge back to the nursing home

Submit answer | Skip question | Tag Question | Remove question

Shop

(Please select 1 option)

○	Contact the police
○	Contact tracing of sexual partners
○	Informal enquiry to the nursing home
◉	Seek advice from the MDU ✓ Correct
○	Treat the patient and discharge back to the nursing home

These ethical questions can be quite tough to answer with accuracy.

This question specifically relates to elder abuse, in this case potential elder sexual abuse. The scenario is one that is often played out in the press, in which a care worker sexually abuses elderly patients in his or her care.

However, you are given very little information here and what you would do is undoubtedly treat the patient and establish how she contracted gonorrhoea.

The question states that she has a profound dementia, suggesting that abuse has occurred rather than consensual sex. Nonetheless, you need to establish the facts. You have a personal duty of care to the patient and next of kin to do this before contacting the police.

It is likely that the police will need to be called but first it would be worth talking things through and obtaining advice from the MDU. The advice may entail investigating the set-up at the nursing home, talking with the next of kin, (and social services if a social worker has been involved) and finely detailing any injuries that may be present on examination.

Only then should the decision to contact the police be made.

A 76-year-old male presents with cognitive impairment and is diagnosed with dementia.

Which of the following is the most probable cause of the dementia?

(Please select 1 option)

◉	Alzheimer's disease ✓ Correct
○	Creutzfeldt-Jacob disease
○	Lewy body dementia
○	Pick's disease
○	Vascular dementia

Dementia is a clinical state characterised by loss of function in multiple cognitive domains beyond what might be expected from normal aging.

Particularly affected areas may be memory, attention, language, and solving.

The most common form of dementia, Alzheimer's disease, accounts for 50-75% of all cases of dementia.

Another 20-30% is due to blood vessel disease (multi-infarct dementia).

The remaining cases result from a variety of less common disorders.

Time taken: 58 mins 18 secs

Question: 24 of 66

A 47-year-old male presents with marked shortness of breath which has deteriorated over the last two weeks.

On examination he has a hard irregular thyroid mass and has some difficulty breathing. There appears to be no retrosternal extension and he appears clinically euthyroid.

What is the most likely diagnosis?

(Please select 1 option)

- Anaplastic carcinoma of thyroid
- Bleed into a thyroid nodule
- Follicular thyroid carcinoma
- Medullary thyroid carcinoma
- Multinodular goitre

A 47-year-old male presents with marked shortness of breath which has deteriorated over the last two weeks.

On examination he has a hard irregular thyroid mass and has some difficulty breathing. There appears to be no retrosternal extension and he appears clinically euthyroid.

What is the most likely diagnosis?

(Please select 1 option)

◉	Anaplastic carcinoma of thyroid ✓ Correct
○	Bleed into a thyroid nodule
○	Follicular thyroid carcinoma
○	Medullary thyroid carcinoma
○	Multinodular goitre

This patient is likely to have anaplastic carcinoma of the thyroid with compression/infiltration of the trachea.

This is unlikely to be a multinodular goitre as this would be unlikely to compress the trachea unless retrosternal and the description is more compatible with a thyroid malignancy.

Medullary thyroid cancer is associated most often with multiple endocrine neoplasia (MEN) II and would be particularly unusual.

Again follicular would be unlikely to produce such marked infiltrative features in such a short period of time. Typically patients with follicular disease would present with a nodule and/or LAP.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 5 mins 31 secs

Question: 25 of 66

Does integrity refer to a virtue that requires the physician to do the following?

(Please select 1 option)

○	Acknowledge and respond to the suffering of patients
○	Ignore irrelevant differences between the physician and the patient
◉	Practise medicine according to intellectual and moral standards of excellence ✓ Correct
○	Risk health and life in the care of patients
○	Treat in the best interests of the patient

Integrity refers to the practise of medicine according to appropriate ethical standards and excellence.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 6 mins 31 secs

Question: 26 of 66

Are ethics defined as the following?

(Please select 1 option)

◉	Codes and statements of professional organisations of physicians about appropriate conduct ✗ Incorrect answer selected
○	Obedience to the law
○	Prescriptions found in Scripture
○	The study of morality ← This is the correct answer
○	The study of the human conscience

Ethics are defined as the study of morality/the philosophical study of moral values and rules.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 6 mins 31 secs

Question: 27 of 66

By which of the following are most deaths determined?

(Please select 1 option)

- Absent pulse.
- Brain stem tests.
- Loss of pupilary reflex.
- The absence of vital signs.
- The coroner.

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 7 mins 23 secs

Question: 27 of 66

By which of the following are most deaths determined?

(Please select 1 option)

○	Absent pulse.
○	Brain stem tests.
◉	Loss of pupilary reflex. ✕ Incorrect answer selected
○	The absence of vital signs. ← This is the correct answer
○	The coroner.

The absence of vital signs is the commonest mode of diagnosing death and entails

- Absent pulse
- Absent heart sounds
- Respiratory arrest and
- Loss of pupillary light reflex.

Brain stem tests are generally reserved for ventilated cases where organ transplantation may be required.

Doctors most commonly diagnose death not the coroner who provides a verdict on the cause of death.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 8 mins 16 secs

Question: 28 of 66

Withholding the truth about a patient's illness is a violation of:

(Please select 1 option)

○	Autonomy ← This is the correct answer
○	Beneficence
○	Informed consent
◉	Infringement of the Human Rights Act ✕ Incorrect answer selected
○	The Bolam principle

By not informing the patient about all the aspects of their illness we are removing their ability to make decisions for themselves. In effect we, and their relatives, are making the decisions for them. This is the removal of their autonomy.

Informed consent relies upon the patient being provided with the information that is generated from the investigations to which he has consented. Justice implies going beyond one's own feelings, prejudices, and desires to find an appropriate balance among conflicting interests.

The Bolam principle is the basis upon which a doctors actions are judged such that they would be considered appropriate and reasonable to those actions that would be performed by a responsible body of their peers in similar circumstances.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 9 mins 23 secs

Question: 29 of 66

A placebo is defined as which of the following?

(Please select 1 option)

- A standard treatment against which a newer treatment is compared
- A substance given as a treatment for a disorder
- A way to deceive a patient into taking a medication
- ◉ An inert substance given as a medicine in an assessment of its suggestive effect ✓ Correct
- The medication given to a patient for a specific type of ailment

A placebo typically produces mainly a psychological effect when administered to a patient or person involved in a trial.

Work Smart Session - MRCP Part 1

Time taken: 8 mins 26 secs

Question: 2 of 66

A 72-year-old man with longstanding Parkinson's comes to the surgery.

He is maintained on high dose l-dopa therapy but is suffering significant on/off phenomena. This is really affecting his life and he feels unable to leave the house and go on excursions with his wife.

Other past history of note includes prostatism for which he takes an alpha-blocker and a 5-alpha reductase inhibitor. He has also suffered a myocardial infarction some five years earlier.

Which one of the following would be the most appropriate next therapeutic option for him?

(Please select 1 option)

○	Amitriptyline
○	Cabergoline ← This is the correct answer
○	Change to soluble levodopa before meals
○	Entacapone
◉	Selegiline ✕ Incorrect answer selected

On/off phenomena may be considerably improved either by the addition of cabergoline (a dopamine agonist) or a subcutaneous infusion of apomorphine.

Liquid forms of l-dopa may also be helpful as they allow closer titration of dose, and splitting meals into smaller snacks and one larger evening meal also affects the pharmacokinetics (PK) of l-dopa positively.

Work Smart Session - MRCP Part 1

Time taken: 8 mins 26 secs

Question: 3 of 66

A patient of yours suffers a myocardial infarction and dies in Spain. His relatives arrange for his body to be repatriated and plan for him to be cremated.

You last saw him alive seven days before his death.

Which of the following is true with respect to completion of cremation forms?

(Please select 1 option)

○	A colleague should complete form 4
○	A cremation may only take place if a coroner rules that no inquest or post mortem is needed
○	The Spanish doctor who originally treated him should complete form 4
○	You are allowed to complete form 5
○	You are allowed to complete forms 4 and 5

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 10 mins 47 secs

Question: 30 of 66

In which of the following cases is the individual's right to autonomy violated?

(Please select 1 option)

- An athlete who seeks a second opinion
- An infant whose parents elect for surgery to correct a congenital heart defect
- An older man whose physician and family coerce him into having foot surgery ✓ Correct
- An older woman who refuses to undergo back surgery
- A Jehovah's witness patient with symptomatic anaemia who refuses blood transfusion

Autonomy refers to an individual's right to be self-governing. Although the procedures may be in the best interests of the patient, if the patient refuses and this refusal is informed, then the doctor or relatives cannot coerce that person into having the procedure.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 11 mins 36 secs

Question: 31 of 66

The need for new methods of defining and determining death was created by what medical procedure?

(Please select 1 option)

○	Artificial resuscitation
○	Brain surgery
◉	ITU ventilation ✗ Incorrect answer selected
○	Open heart surgery
○	Organ transplantation ← This is the correct answer

The conventional criteria previously established for clinical death were based upon cardiac standstill.

Due to the development of organ transplantation those criteria needed revision so that they are now based upon brain stem death.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 13 mins 51 secs

Question: 32 of 66

Which of the following statements is the principal argument made by proponents of making commerce in human organs for legal use?

(Please select 1 option)

○	A person's heirs have the right to earn money by selling the deceased's organs.
○	Commercialisation is not ethically preferable to the gift model of organ donation.
○	It is an ethical trade in a capitalistic society
○	Shortages or surpluses would be eliminated. ← This is the correct answer
◉	There is already an active "black market" in transplantable organs. ✕ Incorrect answer selected

Although particularly controversial the arguments for commercial organ donation suggest that surpluses or deficits in organs would be eliminated and that the current black market in this resource associated with the inherent exploitation of the poor would be resolved.

However it is unethical to exploit live donors in impoverished countries as may happen currently.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 13 mins 51 secs

Question: 33 of 66

A 63-year-old smoker has been investigated for a cough and chest pain and a diagnosis of bronchial carcinoma is made on a plain chest x ray examination.

Before a tissue diagnosis can be made, he dies in hospital of a large and unexpected haemoptysis and a post mortem examination is carried out with the consent of the relatives. At this examination, the correct diagnosis is shown to be tuberculosis and there is no carcinoma.

In this circumstance, it is mandatory to make a report to a particular authority.

Which authority?

(Please select 1 option)

- ○ Consultant in Communicable Diseases Control
- ○ Coroner
- ○ General Medical Council
- ○ Health and Safety Executive
- ○ Strategic Health Authority

Submit answer | Skip question | Tag Question | Remove question

Before a tissue diagnosis can be made, he dies in hospital of a large and unexpected haemoptysis and a post mortem examination is carried out with the consent of the relatives. At this examination, the correct diagnosis is shown to be tuberculosis and there is no carcinoma.

In this circumstance, it is mandatory to make a report to a particular authority.

Which authority?

(Please select 1 option)

◉	Consultant in Communicable Diseases Control ✓ Correct
○	Coroner
○	General Medical Council
○	Health and Safety Executive
○	Strategic Health Authority

There are a number of notifiable infectious diseases that it is mandatory to report to the Consultant in Communicable Diseases Control. They include:

- tuberculosis
- malaria
- meningitis
- meningococcal sepsis.

Question: 34 of 66

An 82-year-old male with longstanding Alzheimer's dementia presents as his carers are concerned about his increased episodes of aggression. Physically he is well.

Which is the most appropriate treatment for his aggressive outbursts?

(Please select 1 option)

- Diazepam
- Quetiapine
- Risperidone
- Temazepam
- Valproate

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

An 82-year-old male with longstanding Alzheimer's dementia presents as his carers are concerned about his increased episodes of aggression. Physically he is well.

Which is the most appropriate treatment for his aggressive outbursts?

(Please select 1 option)

○	Diazepam
◉	Quetiapine ✓ Correct
○	Risperidone
○	Temazepam
○	Valproate

Risperidone used to be a favourite treatment for aggression/agitation in dementia but recent studies indicate that it is associated with an increased mortality and a threefold increased risk of stroke.

Valproate is widely used for its calming effects in this situation but although widely used there is little evidence of the efficacy of valproate.

Valproic acid for agitation in dementia Cochrane Database Syst Rev. 2004;(2):CD003945

Haloperidol may be associated with cardiac arrhythmias, and its use is now discouraged for long term use.

The other options are associated with more prominent adverse effects.

Which of the following apply with regard to obtaining consent for the procedure?

(Please select 1 option)

○	If the mini mental score is above 20/30, consent can be taken from patient
○	Psychogeriatric opinion is needed before consent can be obtained
○	Relatives/next of kin will have to consent for the patient
○	The doctor will be able to consent for the patient
◉	The procedure does not require a written consent ✓ Correct

In this case, which is an emergency, informed written consent is not essential as the procedure is potentially life-saving and the doctor would be seen to be acting in the patient's best interest.

The process of consent for a procedure relies upon written and informed consent which the patient has to understand.

When a patient has impaired mental capacity, the doctor may be uncertain whether the patient is competent to give informed consent. Under English law no other person can consent to treatment on behalf of an adult, though it is desirable that next of kin are consulted before treating an adult without consent.

Recent legislation gives legal authority to people appointed by the patient, or by the state, or a relative or carer, to consent (or refuse) on behalf of the patient.

A mini-mental score may not adequately identify those unable to give consent.

A patient attends for breast screening and asks you the following questions.

Which statement is correct?

(Please select 1 option)

○	Early diagnosis does not change the rate of death from breast cancer
○	In young patients with a BRCA mutation, mammographic screening has a low sensitivity for detecting tumours ← This is the correct answer
○	Mammographic screening is more sensitive in patient groups with denser breast tissue
○	Mammographic screening is offered to all women aged 20-75 years
◉	p53 mutation is a commonly identified in subjects with a strong family history of breast cancer ✕ Incorrect answer selected

In young patients MRI may help to delineate breast cancer in breast tissue which in younger patients is denser than the breast tissue of older patients. Mammography is more sensitive in older patient groups partly because in general the breast tissue is less dense.

Mammographic screening of all women between the ages of 50 and 70 years can reduce mortality from breast cancer by 25%. There is no consensus regarding the value of breast cancer screening among women who are 40- to 49-years-old.

The presence of a germ-line mutation of the BRCA1 or BRCA2 gene increases the risk of breast cancer considerably, and patients with these mutations should be offered the opportunity to receive screening at much younger than 50 years.

p53 mutations are rarely found in patients even with a family history of breast cancer.

Time taken: 1 hrs 19 mins 4 secs

Question: 37 of 66

An 18-year-old male develops thirst, weight loss and polyuria. Investigations confirm that he has type 1 diabetes and he is treated with basal bolus insulin.

He is keen to know what limitations this diagnosis imposes on career opportunities.

Which of the following professions would he not be able to pursue?

(Please select 1 option)

○	Ambulance control centre worker
○	Civil engineer
○	Milkman
○	Physical education instructor
◉	Policeman ✓ Correct

The armed forces, working offshore or aboard ships, air pilot, HGV/PSV licence, police, fire or driving in the post office are career paths closed to subjects with insulin dependent diabetes .

Some local authorities do permit licences to taxi drivers with insulin treated diabetes whilst others do not.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 19 mins 52 secs

Question: 38 of 66

An 85-year-old woman with diabetes mellitus presented with sudden onset of wild flinging movements of the left arm which disappeared during sleep.

What is the most likely explanation?

(Please select 1 option)

◉	Contralateral subthalamic nucleus infarction ✓ Correct
○	Focal motor seizures
○	Hypoglycaemia
○	Ipsilateral caudate nucleus infarction
○	Ipsilateral cerebellar infarction

This is hemiballismus, and in a diabetic patient is likely to be due to a vascular event in the contralateral subthalamic nucleus.

A 75-year-old male presents with a two month history of dyspnoea, weight loss and generalised lethargy. Past medical history included a previous left-sided hemiparesis due to stroke for which he took aspirin and perindopril.

Examination revealed residual left sided hemiparesis together with a pale and slightly jaundiced appearance.

Investigations show:

Haemoglobin	5 g/dL (13.0-18.0)
MCV	109 fL (80-96)
White cell count	2 $x10^9$/L (4-11 $x10^9$)
Platelets	45 $x10^9$/L (150-400 $x10^9$)

- Urinalysis: Increased urobilinogen

What is the next most appropriate investigation?

(Please select 1 option)

- Bone marrow aspirate
- Direct antiglobulin test
- Endoscopy
- Serum haptoglobins
- Vitamin B_{12} concentration

Submit answer | Skip question | Remove Tag | Remove question

Avira
Update was finished successfully.
There were 9 new files installed.
Do not show this message again.
OK

- Urinalysis: increased urobilinogen

What is the next most appropriate investigation?

(Please select 1 option)

○	Bone marrow aspirate
○	Direct antiglobulin test
○	Endoscopy
○	Serum haptoglobins
◉	Vitamin B_{12} concentration ✓ Correct

In this situation, serum B_{12} estimation is the correct choice. With a pancytopenic picture and raised mean corpuscular volume (MCV), the most appropriate step is to check the B_{12} and folate.

The other choices are considered only after the basic assays.

Haemolysis does not explain the low WCC, nor the thrombocytopenia.

A haptoglobin only adds weight to a diagnosis of haemolysis, and a RBC-labelled scan would add greater sensitivity to the diagnosis of haemolysis.

The mild jaundice is typical of megaloblastic anaemia (vitamin B12 or folate deficiency) because of increased destruction of red cell precursors in the bone marrow.

Work Smart Session - MRCP Part 1

Time taken: 9 mins 51 secs

Question: 3 of 66

A patient of yours suffers a myocardial infarction and dies in Spain. His relatives arrange for his body to be repatriated and plan for him to be cremated.

You last saw him alive seven days before his death.

Which of the following is true with respect to completion of cremation forms?

(Please select 1 option)

◉	A colleague should complete form 4 ✕ Incorrect answer selected
○	A cremation may only take place if a coroner rules that no inquest or post mortem is needed ← This is the correct answer
○	The Spanish doctor who originally treated him should complete form 4
○	You are allowed to complete form 5
○	You are allowed to complete forms 4 and 5

Where deaths abroad are concerned, a cremation may only take place if the coroner is satisfied that a post mortem or inquest is not necessary.

It is highly unlikely that you will be in a position to complete forms 4 and 5, and it is not appropriate for form 4 to be completed by the Spanish doctor who originally treated the patient.

Ministry of Justice cremation guidelines

Work Smart Session - MRCP Part 1

Time taken: 9 mins 51 secs

Question: 4 of 66

You are completing a list of cremation form 5s for patients in the hospital where you work.

You examine one form where the junior doctor has completed the cause of death as stroke, but the patient appears to have fallen at home. The husband wants to arrange cremation as soon as possible.

Apparently the junior doctor is working nights and has gone home, so you cannot easily get hold of him to question him further.

Which of the following is true with respect to completion of the form?

(Please select 1 option)

- ○ Completion of form 5 to show that examination of the case has been "adequate" would be acceptable
- ○ It is acceptable in this case not to question the doctor
- ○ Medical referees will not mind if you have not contacted the doctor
- ○ When completing form 5 you must only be reasonably sure that the patient suffered a stroke
- ○ You should wait to complete the form until the doctor is available to answer questions

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 21 mins 22 secs

Question: 40 of 66

A 75-year-old man is awaiting transurethral resection of the prostate, but is brought into hospital in acute urinary retention.

Which of the following drugs might be responsible?

(Please select 1 option)

○	Ipatropium bromide inhaler
○	Montelukast
○	Serevent inhaler
○	Sodium chromoglycate
○	Theophylline

Question: 40 of 66

A 75-year-old man is awaiting transurethral resection of the prostate, but is brought into hospital in acute urinary retention.

Which of the following drugs might be responsible?

(Please select 1 option)

◉	Ipatropium bromide inhaler ✓ Correct
○	Montelukast
○	Serevent inhaler
○	Sodium chromoglycate
○	Theophylline

Ipatropium bromide acts as an antimuscarinic bronchodilator and has traditionally been regarded as more effective in relieving bronchoconstriction associated with chronic bronchitis.

Side-effects are rare and it does not increase sputum viscosity or affect the mucociliary clearance of sputum.

Reported side-effects are dry mouth, blurred vision, constipation and urinary retention.

The nebulised drug has occasionally been reported to leak around the mask and precipitate acute angle closure glaucoma in susceptible patients.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 22 mins 21 secs

Question: 41 of 66

Which of the following statements is true regarding neck of femur fracture?

(Please select 1 option)

○	Extracapsular fractures have a higher incidence of avascular necrosis compared to intracapsular fractures
○	Internal rotation of the affected limb is a common clinical finding
○	In the young displaced fractures should be reduced and fixed urgently
○	Mortality for elderly patients is >80% at one year
○	Non-union is not a complication

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 23 mins 7 secs

Question: 41 of 66

Which of the following statements is true regarding neck of femur fracture?

(Please select 1 option)

○	Extracapsular fractures have a higher incidence of avascular necrosis compared to intracapsular fractures
○	Internal rotation of the affected limb is a common clinical finding
◉	In the young displaced fractures should be reduced and fixed urgently ✓ Correct
○	Mortality for elderly patients is >80% at one year
○	Non-union is not a complication

Intracapsular femoral fractures are at increased risk of avascular necrosis due to disruption of the capsular blood supply at the time of injury.

Patients more commonly present with a short, externally rotated limb.

In young patients the fracture should be reduced and fixed early to decrease the risks of avascular necrosis and non-union.

Mortality at one year is approximately 25%.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Question: 42 of 66

A 80-year-old man presents with deteriorating lumbar and bilateral hip pains. He has recently been seen by his GP with symptoms of prostatism.

Investigations revealed:

Full blood count	Normal	
Corrected calcium	2.3 mmol/l	(2.2-2.6)
ESR	22 mm/1st hr	(1-10)
Alkaline phosphatase	985 U/l	(60-110)
Gamma-GT	33 U/l	(<50)
Prostate specific antigen	6.6 pg/l	(0-6)

What is the most likely cause of this man's pain?

(Please select 1 option)

- Multiple myeloma
- Osteomalacia
- Paget's disease of the pelvis
- Polymyalgia rheumatica (PMR)
- Prostatic carcinoma with metastases

Alkaline phosphatase	985 U/l	(60-110)
Gamma-GT	33 U/l	(<50)
Prostate specific antigen	6.6 pg/l	(0-6)

What is the most likely cause of this man's pain?

(Please select 1 option)

- Multiple myeloma
- Osteomalacia
- Paget's disease of the pelvis ✓ Correct
- Polymyalgia rheumatica (PMR)
- Prostatic carcinoma with metastases

This elderly patient presenting with bone pains has elevated alkaline phosphatase with normal calcium concentrations suggesting a diagnosis of Paget's.

The slightly elevated PSA is in keeping with benign prostatic hypertrophy rather than prostatic malignancy where a PSA of above 10 would be expected.

The normal calcium and only slightly elevated erythrocyte sedimentation rate (ESR) argues against osteomalacia, myeloma and PMR.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

An 80-year-old woman with type 2 diabetes mellitus is referred with weakness.

She had been taking bendroflumethiazide, digoxin and tolbutamide.

On examination she had a temperature of 37.8ºC, a pulse of 98 bpm in atrial fibrillation, and a blood pressure of 118/72 mmHg.

Investigations show:

Sodium	121 mmol/L (137-144)
Potassium	3.3 mmol/L (3.5-4.9)
Urea	4.8 mmol/L (2.5-7.5)
Creatinine	83 µmol/L (60-110)
Glucose	15.2 mmol/L (3.0-6.0)
Chest X-ray	Normal

What is the most likely cause for the hyponatraemia?

(Please select 1 option)

- ○ Addison's disease
- ○ Bendroflumethiazide (bendroflumethiazide)
- ○ Hyperglycaemia
- ○ Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- ○ Tolbutamide

Urea	4.8 mmol/L (2.5-7.5)
Creatinine	83 µmol/L (60-110)
Glucose	15.2 mmol/L (3.0-6.0)
Chest X-ray	Normal

What is the most likely cause for the hyponatraemia?

(Please select 1 option)

○	Addison's disease
○	Bendroflumethiazide (bendroflumethiazide) ← This is the correct answer
○	Hyperglycaemia
◉	Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) ✕ Incorrect answer selected
○	Tolbutamide

This patient has hyponatraemia and hypokalaemia. This is probably due to the bendroflumethiazide which should be stopped.

It is unlikely to be SIADH, of which tolbutamide is a cause, as the hypokalaemia is not typically associated.

Her hyperglycaemia with an osmotic diuresis would cause dehydration.

Addison's disease would be associated with hyperkalaemia, hypotension and elevated urea.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 28 mins 59 secs

Question: 45 of 66

An 80-year-old male presented with acute right-sided weakness.

Examination revealed minimal right facial weakness, impaired elevation of the right shoulder, with relatively preserved right hand strength. There was global weakness in the right leg which appeared to be maximal in the foot.

Which of the following arteries is most likely to have been affected?

(Please select 1 option)

- Anterior cerebral artery
- Lenticulostriate artery
- Middle cerebral artery
- Posterior cerebral artery
- Posterior communicating artery

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

◉	Anterior cerebral artery ✓ Correct
○	Lenticulostriate artery
○	Middle cerebral artery
○	Posterior cerebral artery
○	Posterior communicating artery

It's a tricky question and it is purposely so.

The wording of the description could be due to middle or anterior artery circulation stroke but the challenge is to choose which is the more likely.

The case as described is the classic presentation of an anterior cerebral artery stroke as originally described in the literature. (Critchley M. The anterior cerebral artery and its syndromes. Brain 1930; 53:120-165.)

Unilateral occlusion (distal to ant. comm. origin) of **anterior cerebral artery** produces contralateral sensorimotor deficits mainly involving the lower extremity with relative sparing of face and hands (think of the humunculus).

The lateral lenticulostriate artery is a branch of the middle cerebral artery. Occlusion causes damage to the internal capsule resulting in contralateral hemiparesis and sensory deficit. Speech may be affected (medial temporal lobe) as well as visual function (Meyer's loop: optic radiations affected).

Middle cerebral artery: Occlusion at the stem (proximal segment) results in:

- Contralateral hemiplegia affecting face, arm, and leg (lesser)
- Homonymous hemianopia - ipsilateral head/eye deviation
- If on left: global aphasia

Posterior cerebral artery: A variety of neurological syndromes including:

- Pure hemisensory loss
- Visual field loss- a variety
- Visual agnosia
- Disorders of reading (alexia, dyslexia) and more ...

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 30 mins 14 secs

Question: 46 of 66

An 80-year-old male presented with palpitations of five hours duration.

One month previously he suffered weakness of the right arm and problems with his speech which resolved within four hours. He was taking no medication.

On examination, he was stable with a pulse of 135 beats per minute which was confirmed to be atrial fibrillation on ECG. He had a blood pressure of 112/80 mmHg and appeared clinically euthyroid.

Within one hour he reverted to sinus rhythm spontaneously.

Echocardiogram was normal but a 24 hour ECG revealed three episodes of atrial fibrillation each lasting around ten minutes.

Which one of the following is the most appropriate initial treatment for this patient?

(Please select 1 option)

- Amiodarone
- Aspirin
- Atenolol
- Digoxin
- Warfarin

Submit answer | Skip question | Tag Question | Remove question

taking no medication.

On examination, he was stable with a pulse of 135 beats per minute which was confirmed to be atrial fibrillation on ECG. He had a blood pressure of 112/80 mmHg and appeared clinically euthyroid.

Within one hour he reverted to sinus rhythm spontaneously.

Echocardiogram was normal but a 24 hour ECG revealed three episodes of atrial fibrillation each lasting around ten minutes.

Which one of the following is the most appropriate initial treatment for this patient?

(Please select 1 option)

○	Amiodarone
○	Aspirin
○	Atenolol
○	Digoxin
◉	Warfarin ✓ Correct

The most appropriate initial therapy for this patient who has a high risk of thrombo-embolic stroke is anticoagulation with warfarin maintaining an international normalised ratio (INR) between 2-3.

This should be the initial priority as he has already had one episode of transient ischaemic attack (TIA).

The maintenance of sinus rhythm would be the next step and amiodarone or sotalol are options.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 31 mins 49 secs

Question: 47 of 66

An 81-year-old frail man admitted with a stroke becomes increasingly drowsy after receiving nasogastric (NG) feeding for five days.

Which biochemical abnormality is the most likely cause of his drowsiness?

(Please select 1 option)

- Hyperglycaemia
- Hypermagnesaemia
- Hypernatraemia
- Hypocalcaemia
- Hypophosphataemia

Submit answer | Skip question | Tag Question | Remove question

Question: 47 of 66

An 81-year-old frail man admitted with a stroke becomes increasingly drowsy after receiving nasogastric (NG) feeding for five days.

Which biochemical abnormality is the most likely cause of his drowsiness?

(Please select 1 option)

○	Hyperglycaemia
○	Hypermagnesaemia
○	Hypernatraemia
○	Hypocalcaemia
◉	Hypophosphataemia ✓ Correct

The chronology of his presentation five days after receiving NG feeds suggests hypophosphataemia associated with the re-feeding syndrome.

This is well described in elderly frail subjects who may have prior poor nutrition.

However, other electrolyte abnormalities are also described in association with NG feeds, for example, hypernatraemia.

But with this briefest of histories and the five days it is likely that the examiner is looking for hypophosphataemia.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 32 mins 32 secs

Question: 48 of 66

A 79-year-old male is admitted with acute confusion and is agitated and aggressive to staff.

His relatives who accompany him assert that he had been entirely self-caring, does not drink alcohol and was taking no previous medication. He was diagnosed with a urinary tract infection and commenced antibiotics but remained agitated and distressed.

Which one of the following treatments is the most appropriate for his agitation?

(Please select 1 option)

○	Chlorpromazine
○	Diazepam
○	Quetiapine
○	Temazepam
○	Trazodone

Submit answer | Skip question | Tag Question | Remove question

- Help
- Shop

Which one of the following treatments is the most appropriate for his agitation?

(Please select 1 option)

○	Chlorpromazine
○	Diazepam
◉	Quetiapine ✓ Correct
○	Temazepam
○	Trazodone

The best agent for acute agitation in this elderly patient would be quetiapine probably administered intramuscularly (IM).

Second line management would be lorazepam IM, or even IV.

Temazepam is too short-acting to be administered to this patient and may precipitate respiratory depression whilst diazepam oral has too long a duration of action to be of any use as an acute sedative in the elderly.

Trazodone, an anti-depressant, is useful orally as a chronic anxiolytic.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 33 mins 15 secs

Question: 49 of 66

A 70-year-old woman presented with a relatively short history of headaches and episodic impairment of consciousness.

What is the most likely cause?

(Please select 1 option)

○	Alzheimer-type dementia
○	Chronic subdural haematoma
○	Creutzfeldt-Jacob disease
○	Depressive stupor
○	Normal pressure hydocephalus

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 70-year-old woman presented with a relatively short history of headaches and episodic impairment of consciousness.

What is the most likely cause?

(Please select 1 option)

○	Alzheimer-type dementia
◉	Chronic subdural haematoma ✓ Correct
○	Creutzfeldt-Jacob disease
○	Depressive stupor
○	Normal pressure hydocephalus

This is the classical presentation of subdural haematoma.

Headache, drowsiness and confusion are common and often fluctuate.

Both dementia and depressive stupor (immobile, mute, unresponsive but fully conscious) are not associated with impaired consciousness.

Normal pressure hydocephalus is characterised by dementia, apraxia and urinary incontinence.

Question: 4 of 66

You are completing a list of cremation form 5s for patients in the hospital where you work.

You examine one form where the junior doctor has completed the cause of death as stroke, but the patient appears to have fallen at home. The husband wants to arrange cremation as soon as possible.

Apparently the junior doctor is working nights and has gone home, so you cannot easily get hold of him to question him further.

Which of the following is true with respect to completion of the form?

(Please select 1 option)

○	Completion of form 5 to show that examination of the case has been "adequate" would be acceptable
○	It is acceptable in this case not to question the doctor
○	Medical referees will not mind if you have not contacted the doctor
◉	When completing form 5 you must only be reasonably sure that the patient suffered a stroke ✕ Incorrect answer selected
○	You should wait to complete the form until the doctor is available to answer questions ← This is the correct answer

Doctors are now instructed that form 5 should always be completed after questioning the doctor who completed form 4 except under exceptional circumstances, that is, only if the doctor is seriously ill.

Unavailability of the doctor is not an appropriate excuse, so quite clearly in this case you should wait to complete the form.

The other major principle with respect to completion of form 5 is that you must be absolutely sure that the cause of death is correct.

Ministry of Justice cremation guidelines

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 33 mins 41 secs

Question: 50 of 66

A 60-year-old man presents with an episode of memory loss. Three days earlier he had become confused. His wife led him into the house - he apparently sat down at her request, and had a cup of tea. He then wandered around the house, confused, but remained conscious and able to have some conversation with his wife, though continuing to ask similar questions repeatedly.

After three hours, he abruptly returned to normal and had no recollection of the events.

What is the most likely diagnosis?

(Please select 1 option)

○	Alcohol related amnesia
○	Chronic subdural haematoma
○	Complex partial status epilepticus
○	Hysterical fugue state
◉	Transient global amnesia

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 37 mins 8 secs

Question: 51 of 66

A 45-year-old woman noticed tinnitus in her left ear which progressed over some weeks to hearing loss in that ear.

On physical examination she is found to have a marked decrease in hearing on the left, with Rinne test indicating air conduction better than bone conduction. The other cranial nerves I - VII and IX - XII are intact.

A brain MRI scan revealed a solitary, fairly discreet, 3 cm mass located in the region of the left cerebellopontine angle.

Which of the following statements is most appropriate to tell the patient regarding these findings?

(Please select 1 option)

○	A test for HIV-1 is likely to be positive
○	Other family members should undergo MR imaging of the brain
○	Remissions and exacerbations are likely to occur in coming years
○	The lesion can be resected with a good prognosis
○	You are unlikely to survive for more than a year

Submit answer | Skip question | Tag Question | Remove question

Question: 51 of 66

A 45-year-old woman noticed tinnitus in her left ear which progressed over some weeks to hearing loss in that ear.

On physical examination she is found to have a marked decrease in hearing on the left, with Rinne test indicating air conduction better than bone conduction. The other cranial nerves I - VII and IX - XII are intact.

A brain MRI scan revealed a solitary, fairly discreet, 3 cm mass located in the region of the left cerebellopontine angle.

Which of the following statements is most appropriate to tell the patient regarding these findings?

(Please select 1 option)

○	A test for HIV-1 is likely to be positive
○	Other family members should undergo MR imaging of the brain
○	Remissions and exacerbations are likely to occur in coming years
◉	The lesion can be resected with a good prognosis ✓ Correct
○	You are unlikely to survive for more than a year

These acoustic neuromas are benign neoplasms.

A solitary mass is unlikely to be part of neurofibromatosis (which could be familial).

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 38 mins 54 secs

Question: 52 of 66

A 72-year-old woman has a five year history of worsening mental functioning with trouble remembering things. She has no problems with movement.

She is noted on an MRI scan of the brain to have symmetrically increased size of the lateral ventricles along with cerebral cortical atrophy in a mainly frontal and parietal distribution.

A lumbar puncture reveals a normal opening pressure, and analysis of the clear, colorless cerebrospinal fluid reveals glucose and protein which are in normal ranges.

Cell count on the CSF shows 3 WBCs (all lymphocytes) and 1 RBC.

A fundoscopic examination is normal.

Which of the following findings is most likely associated with her underlying disease process?

(Please select 1 option)

○	Increased numbers of Lewy bodies
○	Loss of Betz cells
○	Loss of gamma aminobutyric acid (GABA)
○	Perivascular mononuclear inflammation
○	Presence of the e4 allele of apolipoprotein E

A lumbar puncture reveals a normal opening pressure, and analysis of the clear, colorless cerebrospinal fluid reveals glucose and protein which are in normal ranges.

Cell count on the CSF shows 3 WBCs (all lymphocytes) and 1 RBC.

A fundoscopic examination is normal.

Which of the following findings is most likely associated with her underlying disease process?

(Please select 1 option)

○	Increased numbers of Lewy bodies
○	Loss of Betz cells
◉	Loss of gamma aminobutyric acid (GABA) ✕ Incorrect answer selected
○	Perivascular mononuclear inflammation
○	Presence of the e4 allele of apolipoprotein E ← This is the correct answer

She has findings characteristic for Alzheimer's disease.

Loss of GABA is seen in Parkinson's disease.

Perivascular mononuclear inflammation is seen in multiple sclerosis.

Loss of Betz cells is seen in motor neurone disease.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 41 mins 51 secs

Question: 53 of 66

A 35-year-old healthy woman has a faint systolic murmur on physical examination. An echocardiogram is performed, and she is found to have a bicuspid aortic valve.

In explaining the meaning of this finding to her, which is the most appropriate statement?

(Please select 1 option)

○	An aortic valve replacement is eventually likely to be required
○	Other family members are likely to have the same condition
○	She should be treated with a cholesterol-lowering agent
○	The problem has resulted from past injection drug usage
○	This is one manifestation of an underlying autoimmune disease process

A 35-year-old healthy woman has a faint systolic murmur on physical examination. An echocardiogram is performed, and she is found to have a bicuspid aortic valve.

In explaining the meaning of this finding to her, which is the most appropriate statement?

(Please select 1 option)

◉	An aortic valve replacement is eventually likely to be required ✓ Correct
○	Other family members are likely to have the same condition
○	She should be treated with a cholesterol-lowering agent
○	The problem has resulted from past injection drug usage
○	This is one manifestation of an underlying autoimmune disease process

Bicuspid aortic valve (BAV) is perhaps the most common form of congenital heart disease in adults (1-2% of population).

Bicuspid valves have a propensity to wear out and calcify with ageing. Bicuspid aortic valve tends to be sporadic although there is a reported familial incidence of approximately 9%.

From a review of several sources in the literature, the Aeromedical Consultation Service (ACS) at Brooks AFB calculated a 1.2% per year incidence of aortic valve surgery in individuals with BAV, although the vast majority occur in the fifth and sixth decades of life.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 43 mins 6 secs

Question: 54 of 66

A 74-year-old man has had increasingly severe, throbbing headaches for several months, centered on the right.

There is a palpable tender cord-like area over his right temple. His heart rate is regular with no murmurs, gallops, or rubs. Pulses are equal and full in all extremities, BP is 110/85 mmHg.

A biopsy of this lesion is obtained, and histologic examination reveals a muscular artery with lumenal narrowing and medial inflammation with lymphocytes, macrophages, and occasional giant cells.

He improves with a course of high-dose corticosteroid therapy.

Which of the following laboratory test findings is most likely to be present with this disease?

(Please select 1 option)

○	Anti-double stranded DNA titre of 1:1024
○	Erythrocyte sedimentation rate of 110 mm/hr
○	HDL cholesterol of 0.6 mmol/L
○	pANCA titre of 1:160
○	Rheumatoid factor titre of 80 IU/mL

rubs. Pulses are equal and full in all extremities; BP is 110/65 mmHg.

A biopsy of this lesion is obtained, and histologic examination reveals a muscular artery with lumenal narrowing and medial inflammation with lymphocytes, macrophages, and occasional giant cells.

He improves with a course of high-dose corticosteroid therapy.

Which of the following laboratory test findings is most likely to be present with this disease?

(Please select 1 option)

○	Anti-double stranded DNA titre of 1:1024
◉	Erythrocyte sedimentation rate of 110 mm/hr ✓ Correct
○	HDL cholesterol of 0.6 mmol/L
○	pANCA titre of 1:160
○	Rheumatoid factor titre of 80 IU/mL

These are classic findings for temporal arteritis, the most typical involvement with giant cell arteritis.

Corticosteroid therapy typically produces a reduction of symptoms.

Not treating this condition puts the patient at risk for involvement of other branches of the external carotid artery, the worst of which would be the ophthalmic branch.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 44 mins 35 secs

Question: 55 of 66

A 70-year-old woman presented with episodic impairment of consciousness.

Which of the following is the most likely cause?

(Please select 1 option)

○	Alzheimer type dementia
○	Chronic subdural haematoma
○	Creutzfeldt-Jakob disease
○	Depressive stupor
○	Normal pressure hydrocephalus

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 70-year-old woman presented with episodic impairment of consciousness.

Which of the following is the most likely cause?

(Please select 1 option)

○	Alzheimer type dementia
◉	Chronic subdural haematoma ✓ Correct
○	Creutzfeldt-Jakob disease
○	Depressive stupor
○	Normal pressure hydrocephalus

This is quite a grey question. The clinical scenario is very brief with no mention of any neurological signs so a logical deduction must be made.

Alzheimer's disease would be expected to have a continous impairment of consciousness in its advanced stages but could be episodic if there were variation in drugs therapy or concurrent illnesses.

Similarly normal pressure hydrocephalus, Creutzfeldt-Jakob and depression would present with dementia (or apparent dementia) but not fluctuant.

Of all those listed, subdural haematoma is classically associated with fluctuating level of consciousness. This would make it the most likely.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 45 mins 8 secs

Question: 56 of 66

A 72-year-old male presented with a quadrantic hemianopia.

Which of the following conditions is most likely to cause such a presentation?

(Please select 1 option)

- A lesion of the occipital cortex
- A lesion of the optic chiasma
- Bilateral diabetic retinopathy
- Chloroquine poisoning
- Tobacco amblyopia

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Question: 56 of 66

A 72-year-old male presented with a quadrantic hemianopia.

Which of the following conditions is most likely to cause such a presentation?

(Please select 1 option)

○	A lesion of the occipital cortex ← This is the correct answer
◉	A lesion of the optic chiasma ✕ Incorrect answer selected
○	Bilateral diabetic retinopathy
○	Chloroquine poisoning
○	Tobacco amblyopia

A lesion of the optic chiasm would cause a bitemporal hemianopia.

Diabetic retinopathy may cause an 'apparent quadrantic hemianopia' because the distribution of the retinal changes may just correspond to quadrantic hemianopia - but this is not the most likely.

Tobacco amblyopia causes symmetric central or centrocaecal scotomas.

Chloroquine poisoning causes symmetric bilateral scotomas.

Work Smart Session - MRCP Part 1

Question: 57 of 66

Which of the following features is characteristic of early Alzheimer's disease?

(Please select 1 option)

○	Ataxic gait
◉	Impaired short term memory ✓ Correct
○	Myoclonic jerks
○	Urinary incontinence
○	Visual hallucinations

Alzheimer's disease is characterised early in the disease by short term memory loss.

The other features listed here would suggest an alternative diagnosis such as:

- normal pressure hydrocephalus (gait ataxia and urinary incontinence),

- Creutzfeld-Jacob disease (myoclonic jerks) and

- delirium or vascular dementia (visual hallucinations).

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 46 mins 57 secs

Question: 58 of 66

Which one of the following is associated with parkinsonian features?

(Please select 1 option)

○	Chronic carbon dioxide retention
○	Kernicterus
○	Lead poisoning
○	Mercury poisoning
○	Wilson's disease

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

◉	Chronic carbon dioxide retention ✕ Incorrect answer selected
○	Kernicterus
○	Lead poisoning
○	Mercury poisoning
○	Wilson's disease ← This is the correct answer

Poisons that can cause parkinsonism include:

- manganese
- carbon monoxide
- carbon disulfide
- the cycad nut and
- the illicit drug MPTP (methyl-phenyl tetrahydropyridine).

There are also other diseases of the brain that combine parkinsonism.

These include:

- Wilson's disease
- Huntington's disease
- Shy-Drager syndrome
- striatonigral degeneration
- olivo-ponto-cerebellar degeneration
- cortical-basal ganglionic degeneration
- progressive supranuclear palsy
- diffuse Lewy body disease
- Creutzfeldt-Jacob disease and even
- Alzheimer's disease.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 47 mins 48 secs

Question: 59 of 66

Which one of the following is a recognised feature of achondroplasia?

(Please select 1 option)

- Autosomal recessive inheritance
- May be diagnosed radiologically at birth
- Increased liability to pathological fractures
- Shortened spine
- Subfertility

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which one of the following is a recognised feature of achondroplasia?

(Please select 1 option)

◉	Autosomal recessive inheritance ✗ Incorrect answer selected
○	May be diagnosed radiologically at birth ← This is the correct answer
○	Increased liability to pathological fractures
○	Shortened spine
○	Subfertility

Achondroplasia an autosomal dominant condition and one of the commonest forms of inherited dwarfism.

Epiphyseal dysplasia - thin zone of cartilage cells, diminished columnar arrangement short thick bones, spinal length almost always normal.

Features - short limbs, normal trunk, large head, saddle nose, exagerrated lumbar lordosis normal mental and sexual development, spinal problems.

Homozygotes - neonatal death.

Work Smart Session - MRCP Part 1

Time taken: 14 mins 53 secs

Question: 5 of 66

A female patient of yours unfortunately goes into premature labour at 23 weeks. The fetus is not viable. She wishes to have the fetal remains cremated.

Which of the following is true with respect to legal aspects of this case?

(Please select 1 option)

○	Cremation of the remains is not subject to the Cremation Act ← This is the correct answer
○	Only a pathologist is allowed to complete form 4
○	Only form 4 need be completed
○	Only form 5 need be completed
◉	The case must be discussed with the coroner ✕ Incorrect answer selected

Cremation of fetal remains under 24 weeks is not subject to the Cremation Act.

As such, forms 4 and 5 should not be completed.

In spite of this, most crematoria are happy to make arrangements to cremate fetal remains.

Where body parts are removed at post mortem, arrangements for cremation of these are normally made by the pathology service.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 49 mins 18 secs

Question: 60 of 66

Which of the following is a recognised feature of polymyalgia rheumatica?

(Please select 1 option)

○	Weakness of distal muscle groups
○	Elevated serum creatine phosphokinase activity
○	An association with bronchial carcinoma
◉	Weight loss ✓ Correct
○	A peak incidence in the fourth decade of life

A. Stiffness and weakness is more typical of polymyositis.

B. This would suggest polymyositis.

C. This is typical.

E. It occcurs later in life.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 49 mins 18 secs

Question: 61 of 66

A 60-year-old man with a past history of controlled hypertension presents with acute onset weakness of his left arm, that resolved over 12 hours. He had suffered two similar episodes over the last three months.

Examination reveals a blood pressure of 132/82 mmHg and he is in atrial fibrillation with a ventricular rate of 85 per minute. CT brain scan is normal.

What is the most appropriate management?

(Please select 1 option)

- Amiodarone
- Aspirin
- Digoxin
- Dipyridamole
- Warfarin

Submit answer | Skip question | Tag Question | Remove question

Question: 61 of 66

A 60-year-old man with a past history of controlled hypertension presents with acute onset weakness of his left arm, that resolved over 12 hours. He had suffered two similar episodes over the last three months.

Examination reveals a blood pressure of 132/82 mmHg and he is in atrial fibrillation with a ventricular rate of 85 per minute. CT brain scan is normal.

What is the most appropriate management?

(Please select 1 option)

○	Amiodarone
○	Aspirin
○	Digoxin
○	Dipyridamole
◉	Warfarin ✓ Correct

This patient has had three transient ischaemic attacks due to atrial fibrillation.

The most appropriate therapeutic strategy for this patient would be warfarin. Studies reveal that warfarin would be therapeutically superior to aspirin in such a patient's case.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 50 mins 26 secs

Question: 62 of 66

A 19-year-old woman presents to the clinic having had five blackouts over the last year, all while she is standing up.

She gets warnings of blurred vision, nausea, and feeling hot. She has been witnessed twice to have jerking of all limbs while she is unconscious. The attacks last 30 to 60 seconds.

She recovers quickly after the attacks. She has never bitten her tongue or sustained any injuries.

Physical examination and an ECG are normal. Her grandmother and sister suffer from epilepsy.

Which of the following investigations is the most appropriate?

(Please select 1 option)

○	24 hour ECG recording
○	CT brain
○	ECHO
○	EEG
◉	Tilt table test

Submit answer | Skip question | Tag Question | Remove question

- Shop

Which of the following investigations is the most appropriate?

(Please select 1 option)

○	24 hour ECG recording
○	CT brain
○	ECHO
○	EEG
◉	Tilt table test ✓ Correct

The most likely diagnosis is vasovagal syncope.

The gradual onset of the attack is typical. It is common for patients with syncope to have jerking of their limbs while they are unconscious.

Warning symptoms of darkening/blurring of vision, dizziness, an feeling hot, are characteristic in syncope. Patients usually recover very quickly after the event.

Tilt table test is a useful test to support the diagnosis of vasovagal syncope.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 54 mins 1 secs

Question: 63 of 66

Temporal lobe lesions cause:

(Please select 1 option)

○	Apraxia
○	Astereognosis
○	Primitive reflexes
○	Visuospatial neglect
◉	Wernicke's (receptive) aphasia

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Apraxia
○	Astereognosis
○	Primitive reflexes
○	Visuospatial neglect
◉	Wernicke's (receptive) aphasia ✓ Correct

Lesions of the frontal lobe include difficulties with task sequencing and executive skills.

Other symptoms include:

- expressive aphasia (receptive aphasias are due to a temporal lobe lesion)

- primitive reflexes

-perseveration (repeatedly asking the same question or performing the same task)

- anosmia and

- changes in personality.

Lesions of the parietal lobe include:

- apraxias

- neglect

- astereognosis (unable to recognise an object by feeling it) and

- visual field defects (typically homonymous inferior quadrantanopia).

They may also cause alcalculia (inability to perform mental arithmetic).

Lesions of the temporal lobe cause:

- changes in personality.

Lesions of the parietal lobe include:

- apraxias

- neglect

- astereognosis (unable to recognise an object by feeling it) and

- visual field defects (typically homonymous inferior quadrantanopia).

They may also cause alcalculia (inability to perform mental arithmetic).

Lesions of the temporal lobe cause:

- visual field defects (typically homonymous superior quadrantanopia)

- Wernicke's (receptive) aphasia

- auditory agnosia, and

- memory impairment.

Occipital lobe lesions include:

- cortical blindness (blindness due to damage to the visual cortex and may present as Anton syndrome where there is blindness but the patient is unaware or denies blindness)

- homonymous hemianopia and

- visual agnosia (seeing but not percieving objects - it is different to neglect since in agnosia the objects are seen and followed but cannot be named).

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 54 mins 45 secs

Question: 64 of 66

A 62-year-old lady is suffering from pain and stiffness of her shoulders and difficulty getting out of a chair.

Which of the following would support a diagnosis of polymyalgia rheumatica?

(Please select 1 option)

- Ankle stiffness
- Low grade fever
- Muscle tenderness
- Proximal muscle weakness
- Weight gain

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

○	Ankle stiffness
○	Low grade fever ← This is the correct answer
○	Muscle tenderness
◉	Proximal muscle weakness ✕ Incorrect answer selected
○	Weight gain

Polymyalgia rheumatica presents with early morning stiffness of the shoulder and pelvic girdles, fever, anorexia, weight loss and malaise.

There is no muscle tenderness or weakness and the feet are never affected.

Investigations may reveal:

- Normochromic / normocytic anaemia
- Raised erythrocyte sedimentation rate (ESR) often > 50 mm/hr
- Raised alkaline phosphatase (ALP) and
- Raised C-reactive protein (CRP).

Features of giant cell arteritis should be sought:

- Headache
- Visual disturbance
- Transient ischaemic attacks (TIAs)
- Jaw claudication and
- Thickened, tender, pulseless temporal arteries.

Diagnosis is by temporal artery biopsy and/or characteristic response to steroids.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 59 mins 44 secs

Question: 65 of 66

Osteomalacia may be expected in:

(Please select 1 option)

○	Auto-immune adrenalitis
◉	Mercury poisoning ✓ Correct
○	Pernicious anaemia
○	Pseudo-hypoparathyroidism
○	Sarcoidosis

Osteomalacia may occur with vitamin D deficiency.

Mercury poisoning or any heavy metal poisoning causes an acquired Fanconi syndrome with distal renal tubular acidosis.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 59 mins 44 secs

Question: 66 of 66

A 72-year-old lady has four months of memory loss, urinary incontinence and falls.

On examination she has mild memory loss and a broad-based, slow gait. Muscle tone is normal and both plantar reflexes are downgoing.

What is the likely diagnosis?

(Please select 1 option)

○	Alzheimer's disease
○	Frontal lobe dementia
○	Multi-infarct dementia
○	Normal-pressure hydrocephalus
○	Parkinson's disease

Submit answer | Skip question | Tag Question | Remove question

On examination she has mild memory loss and a broad-based, slow gait. Muscle tone is normal and both plantar reflexes are downgoing.

What is the likely diagnosis?

(Please select 1 option)

○	Alzheimer's disease
○	Frontal lobe dementia
○	Multi-infarct dementia
◉	Normal-pressure hydrocephalus ✓ Correct
○	Parkinson's disease

Normal-pressure hydrocephalus is characterised by abnormal gait, urinary incontinence, and dementia.

It is an important clinical diagnosis, because it is a potentially reversible cause of dementia.

It is important to distinguish it from Parkinson's disease.

The onset of gait disturbance and urinary symptoms is unusual so early in dementia.

Frontal lobe dementia is characterised by loss of 'executive' functions and multi-infarct state usually has a step-wise history.

Finish

You are the general practitioner of a 76-year-old man who has been suffering from bronchial carcinoma for the past one and a half years. He is requiring increasing amounts of morphine to cope with his pain, and he dies in his sleep.

You certify the cause of death as bronchial carcinoma.

His wife who requests cremation asks to see form 4.

Which of the following is true with respect to her viewing the form?

(Please select 1 option)

○	She is not allowed to view it under any circumstances
○	The form should be typewritten if possible
○	The name of the completing doctor must be obscured
○	You can apply for certain information not to be disclosed by discussing this with the referee ← This is the correct answer
◉	You cannot prevent her from reviewing all aspects of the form ✕ Incorrect answer selected

The recent cremation regulations detail that the cremation applicant can view the form.

There may be circumstances though when you wish for certain information not to be disclosed, that the patient may have told you in confidence. In this case you can write to the cremation referee requesting that certain pieces of information are withheld.

When you complete the form it is important that you remember the information may be seen by a relative; also make sure that your handwriting is as legible as possible.

Work Smart Session - MRCP Part 1

Time taken: 19 mins 56 secs

Question: 7 of 66

You are working for the elderly care team in the hospital when an 82-year-old woman under your care is found dead by the nursing staff in the early hours of the morning.

She was not resuscitated due to a history of severe chronic obstructive pulmonary disease (COPD).

You have written the cause of death as old age and you complete cremation form 4.

Which of the following is true with respect to completion of the forms?

(Please select 1 option)

- Civil proceedings have been taken against doctors who have inappropriately completed form 5
- Old age is usually not an acceptable cause of death for cremation purposes when completing form 4
- The consultant who heads up the team may complete form 5
- The locum staff grade who qualified three years ago in India may sign form 5
- Your brother who is a house officer on another team at the hospital may sign form 5

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

the early hours of the morning.

She was not resuscitated due to a history of severe chronic obstructive pulmonary disease (COPD).

You have written the cause of death as old age and you complete cremation form 4.

Which of the following is true with respect to completion of the forms?

(Please select 1 option)

○	Civil proceedings have been taken against doctors who have inappropriately completed form 5
◉	Old age is usually not an acceptable cause of death for cremation purposes when completing form 4 ✓ Correct
○	The consultant who heads up the team may complete form 5
○	The locum staff grade who qualified three years ago in India may sign form 5
○	Your brother who is a house officer on another team at the hospital may sign form 5

A key point with respect to completing form 4 is that the cause of death must be accurately established.

Whilst old age may be acceptable when certifying for a burial, it is not accepted by cremation referees.

The latest guidelines for doctors include specific instructions that members of the same hospital team as the physician completing part 4 must not complete the form, nor may partners in the same GP practice complete the form either.

Additionally, relatives of the patient are forbidden from completing either form 4 or 5, and relatives of the doctor who completes form 4 cannot complete form 5.

Work Smart Session - MRCP Part 1

Time taken: 21 mins 37 secs

Question: 8 of 66

An 85-year-old patient presents with recurrent falls and a fracture of the distal ulna.

Which of the following statements is correct?

(Please select 1 option)

○	Bone fractures attributable to vitamin D deficiency are due to bone density
○	Low Vitamin D levels are not associated with muscle weakness
○	The toxic levels of Vitamin D occur at approximately twice the therapeutic dose
○	Vitamin D deficiency in the elderly is rare
○	Vitamin D replacement reduces the incidence of fractures in the elderly

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Low Vitamin D levels are not associated with muscle weakness
○	The toxic levels of Vitamin D occur at approximately twice the therapeutic dose
○	Vitamin D deficiency in the elderly is rare
◉	Vitamin D replacement reduces the incidence of fractures in the elderly ✓ Correct

The clue is in the question!

Vitamin D deficiency in the elderly is common, especially in the housebound and those in residential and nursing homes, with an overall frequency of 17% in women aged 85 and over.

Vitamin D deficiency is associated with muscle weakness, as well as osteomalacia, and fractures among elderly people with vitamin D deficiency are often not attributable to reduced bone density.

Vitamin D replacement (800 IU daily) with calcium, has been shown to reduce falls and fractures by 47% compared with controls who received calcium only.

The correct dose of vitamin D replacement should be 800 IU.

Lowest doses at which adverse events have been observed with Vitamin D replacement are 200 nmol/l, which equates to a daily dose of 40,000 IU. See BMJ 2005;330:524-6.

Work Smart Session - MRCP Part 1

Time taken: 23 mins 33 secs

Question: 9 of 66

You are asked to see a young man with a severe laceration to his arm.

Before you suture the wound, the patient tells you that he is HIV positive but asks you not to write it in his notes.

He tells you later in the conversation that he is a theatre nurse in a neighbouring hospital. He says that he has not told his employer about his HIV status as it does not impact on his work, and tells you that if you tell anybody he will "get you" for discrimination.

Which of the following is the most appropriate action that should be taken in this case?

(Please select 1 option)

○	Doctors should never inform a third party that a patient is HIV positive without the express consent of the patient.
○	You should arrange for the patient to have an HIV test and confirm the diagnosis before considering breaching his confidentiality.
○	You should discuss with your consultant and, if you feel the patient is practising in a way that places patients at risk, inform the occupational health department at his employing hospital, having informed the patient that you intend to do so.
○	You should tell the hospital infectious diseases consultant in order that the patient can be offered ongoing treatment for HIV
○	You should tell the patient that in your opinion he should inform his employer, but take no action yourself.

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	You should arrange for the patient to have an HIV test and confirm the diagnosis before considering breaching his confidentiality.
◉	You should discuss with your consultant and, if you feel the patient is practising in a way that places patients at risk, inform the occupational health department at his employing hospital, having informed the patient that you intend to do so. ✓ Correct
○	You should tell the hospital infectious diseases consultant in order that the patient can be offered ongoing treatment for HIV
○	You should tell the patient that in your opinion he should inform his employer, but take no action yourself.

You should discuss this with your consultant.

You have a duty as a doctor to protect all patients, not only your own, and this duty must be weighed against your duty of confidentiality to this patient.

The GMC expect doctors to breach confidentiality in certain circumstances where failing to do so may expose the patient or others to risk of death or serious harm, for example where a healthcare worker is practising in a way that places patients at risk.

As a doctor you may be called upon to justify your decision to disclose (or indeed to not disclose), and it would certainly be helpful to take senior advice.

If you decide to disclose information without consent, you should disclose the minimum necessary information to the minimum number of people for purpose.

In this case you may consider disclosing to the occupational health physician in the hospital where the patient works, although you may also consider disclosing the information to the nurses' regulatory body, the Nursing and Midwifery Council.

Part 3 continued

Age at date of death

Sex

☐ Male ☐ Female

Status

☐ married/civil partnership ☐ widow/widower/surviving civil partner ☐ Single

Part 4 The application

1. Are you a near relative or an executor of the person who has died? ☐ Yes ☐ No

Near relative means the widow, widower or surviving civil partner of the person who has died, or a parent or child of the person who has died, or any other relative usually residing with the person who has died.

If No, please give the nature of your relationship and explain why you are making the application rather than a near relative or an executor.

2. Is there any near relative(s) or executor(s) who has not been informed of the proposed cremation? ☐ Yes ☐ No

If Yes, please give the name(s) and the reason(s) why they have not been contacted.

3. Has any near relative or executor expressed any objection to the proposed cremation? ☐ Yes ☐ No

If Yes, please give details.

4. What was the date and time of death of the person who has died?

Date ☐☐/☐☐/☐☐☐☐

Time

continued over the page

Part 4 continued

5. Please give the address where the person died.

Address

Please state whether it was the residence of the person who has died or a hotel, hospital, or nursing home etc.

- ☐ Their home
- ☐ Hospital
- ☐ Other (please specify)
- ☐ Hotel
- ☐ Nursing home

6. Do you know or suspect that the death of the person who has died was violent or unnatural? ☐ Yes ☐ No

7. Do you consider that there should be any further examination of the remains of the person who has died? ☐ Yes ☐ No

If you have answered Yes to questions **6** or **7**, please give reasons below.

8. What is the name, address and telephone number of the usual doctor of the person who has died?

Doctor's name

Address

Telephone number

continued over the page

9. Please give the name, address and telephone number of the doctor(s) who attended the person who has died during their last illness.

Doctor's name

Address

Telephone number

Doctor's name

Address

Telephone number

10. Was any implant placed in the body which may become hazardous when the body is cremated (e.g. a pacemaker, radioactive device or "Fixion" intramedullary nailing system)?

☐ Yes ☐ No

☐ I don't know

Implants may damage cremation equipment if not removed from the body of the deceased before cremation and some radioactive treatments may endanger the health of crematorium staff.

If Yes, please give details and state whether it has been removed.

Part 5 Inspection of certificates

You are entitled to inspect the certificates (if any) given by doctors under regulation 16(c)(i) of the Cremation Regulations 2008 (forms Cremation 4 and Cremation 5). If you do not wish to inspect any such certificates yourself you may nominate another person to inspect them instead of you.

Such certificates will only be available for inspection at the offices of the cremation authority for **48 hours** from the time that the cremation authority notifies you, or the person you have nominated, that the certificates are available to be inspected. You may take someone with you when you attend to inspect the certificates. If you, or the person nominated by you, do not attend to inspect the certificates at the time agreed with the cremation authority, the cremation may then proceed.

Please state if you would like to inspect the certificates given by the doctors or whether you would like to nominate someone else to do so instead and give a contact telephone number.

If certificates are given by medical practitioners:-

☐ I would like to inspect the certificates and

my contact telephone number is

☐ I nominate

to inspect the certificates and their contact telephone number is

---

Part 6 Statement of truth

I apply for the body of the person who has died to be cremated and I certify that I am at least 16 years of age.

I believe that the facts given in this application are true. I am aware that it is an offence to wilfully make a false statement with a view to obtaining the cremation of any human remains.

Authorisation of cremation of deceased person by medical referee

Cremation 10
replacing Form F
01.09

Please complete this form in full, if a part does not apply enter 'N/A'.

Part 1 Details of the deceased

Full name

Address

Occupation or last occupation if retired or not in work at date of death

Part 2 Authorisation by medical referee

An application has been made for the cremation of the remains of the deceased.

I am satisfied that—

(a) the requirements of the Cremation (England and Wales) Regulations 2008 have been complied with;

(b) the inquiry/examination made by the persons who gave the relevant certificates has been adequate; and

(c) the fact and cause of death have been definitely ascertained or, if not ascertained, a coroner has opened an inquest.

Accordingly, I authorise the Registrar of the following crematorium to cremate the remains of the deceased within that crematorium—

Name of crematorium

Regulation 23(1) of the Cremation (England and Wales) Regulations 2008

Certificate after post-mortem examination

Please complete this form in full, if a part does not apply enter 'N/A'.

Part 1 Details of the deceased

Full name

Address

Occupation or last occupation if retired or not in work at date of death

Part 2 Certification of person making post-mortem examination

I certify that I have made a post-mortem examination of the remains of the deceased under the authority of a licence granted under the Human Tissue Act 2004 for that purpose and the appropriate consents required by that Act having been obtained.

I am satisfied that the cause of death was

1. (a) Disease or condition directly leading to death (this does not mean the mode of dying, such as heart failure, asphyxia, asthenia, etc: it means the disease, injury, or complication which caused death)

(b) Other disease or condition, if any, leading to (a)

(c) Other disease or condition, if any, leading to (b)

continued over the page

Part 2 continued

2. Other significant conditions contributing to the death but not related to the disease or condition causing it.

☐ I am satisfied that there is no reason for making any toxicological analysis.

If a toxicology analysis has been made have the results been stated in this certificate or are they attached?

☐ stated in this certificate
☐ attached to this certificate

☐ I am satisfied that there is no reason for the holding of an inquest.

If the cause of death is such as to require that an inquest be held, the coroner should issue a certificate and meet the costs of the post-mortem examination by paying the fee prescribed by the Secretary of State.

I am aware that it is an offence to wilfully make a false statement with a view to obtaining the cremation of any human remains.

Regulation 20(1)(c)(i) of the Cremation (England and Wales) Regulations 2008

Ministry of JUSTICE

Cremation Regulations 2008

Your right to inspect the medical certificates

7 November 2008

Cremation Regulations 2008

Your right to inspect the medical certificates

You have applied for cremation and that means that you have the right to inspect the medical forms about the death of the deceased. Inspection of the forms will take place before the cremation is authorised by the medical referee (that is the doctor attached to the crematorium).

Part 5 of the application form deals with this right. Please read it carefully. The funeral director will have explained this right to you, but you might find it helpful to have something in writing as well.

There are two medical forms. One is completed by the doctor who treated the deceased during his or her last illness, the other by a doctor who did not and who is independent of the first doctor. The second doctor has to examine the deceased, and discuss the death with the first doctor and at least one other person.

If you know the cause of death and have no problems with that cause you may decide that there is very little reason why you need to inspect these forms. However, if you do have doubts or were surprised that the death happened when it did, you may decide that you would like to inspect them.

You can nominate someone else to inspect the forms on your behalf. You might want to do this, for example, if you think someone else would be in a better position to go through the forms (perhaps because that person was present at the death and you were not).

If you already have serious concerns about the death and believe the case should be investigated by a coroner, you should contact the coroner’s office right away. Your funeral director will be able to provide contact details and other assistance. Where the death is unnatural or violent, it should have already been referred to a coroner by a doctor or by the police.

The forms will be available for inspection at the crematorium office for up to 48 hours after you are informed that they have been received there. It is important that you can be contacted during this period.

The medical referee may be able to give you advice on the cause of death, but he or she may charge a fee for this service. As the referee is often also a working doctor, you will need to take account of this when arranging the meeting.

If you want the funeral to be held within the next two or three days, it could be difficult to do this and also inspect the medical forms.

Ministry of JUSTICE

Cremation Regulations 2008

Guidance for cremation authorities and crematorium managers

3 November 2008

Contents

The new regulations	2
Cremation of non-viable foetal remains	2
The forms	3
Annex A	4
Further information	9
Annex B	10

The new regulations

1. The Cremation Regulations 2008 come into effect on 1 January 2009. They modernise and consolidate all previous regulations, replacing the Cremation Regulations 1930 as amended. A copy of the regulations is attached to this guidance. The previous forms may be used for a transitional period of one month, that is until 31 January 2009.

2. All cremation managers should familiarise themselves with the text of the new regulations. There are very few policy changes which require different procedures. The only significant one is that applicants now have the right to inspect the medical forms (forms Cremation 4 and Cremation 5) before the medical referee authorises the cremation. We expect the numbers of applicants wishing to exercise this right to be relatively low but we will keep the position under close review. Where a post-mortem examination is requested by the medical referee, we also consider that the applicant should, on request, be able to have a copy of the post mortem examination report.

3. A more minor change is that the countersignature on the application form is no longer required.

4. The forms make it clear that it is a criminal offence under the Cremation Act 1902 to wilfully make a false statement in order to procure a cremation.

Cremation of non-viable foetal remains

5. Foetal remains under 24 weeks gestation are not subject to the provisions of the Cremation Act or regulations. Further information about the disposal of such remains is published by the Human Tissue Authority and the Stillbirth and Neonatal Death Society (SANDS).

(See the Human Tissue Authority Code of Practice, ‘The removal, storage and disposal of human organs and tissue (Code 5), published July 2006; and the SANDS ‘Pregnancy Loss and Death of Baby – Guidelines for Professionals’, chapters 16 and 17 (hard copies are available from SANDS Head Office 020 7436 7940.)

The forms

6. It is important that you fully adhere to the statutory wording on the forms. The only adaptations which you may make are to add the name and address of the crematorium together with contact details. You should not add marginal notes or explanations. Medical referees have been instructed to reject forms which do not follow the statutory wording.

7. There are 13 forms which are explained at **Annex A**.

Annex A

Form Cremation 1 – Application for Cremation of Remains of Deceased Person (replacing form A)

1. Cremation managers should ensure that all parts of the form have been completed before the form is passed to your medical referee. However, a form should not be rejected solely because, for example, the applicant does not know the postcode of the place of death or deceased person's medical practitioner. We are encouraging funeral directors to assist applicants in providing such information.

2. Question 10 asks about hazardous implants. The medical referee will need to check the information provided carefully and compare it with that provided by the certifying doctor. The funeral director may also be able to provide information or confirm that the implant has been removed.

3. Part 5 of the form deals with applicants' **right to inspect** the medical forms (forms Cremation 4 and Cremation 5) before the medical referee authorises cremation. We expect funeral directors to advise the applicant of the right in neutral terms and neither to encourage nor deter applicants from exercising it (we have suggested a form of wording). Clearly if the death needs to be referred to the coroner after form Cremation 1 has been completed, and it then requires a post-mortem examination to be held or an inquest to be opened, the right of inspection will no longer apply as there will be no forms Cremation 4 and Cremation 5 to inspect.

4. To avoid any delay to the funeral by the applicant inspecting the forms, you should encourage funeral directors and medical practitioners to ensure that the forms Cremation 1, Cremation 4 and Cremation 5 are received as soon before the date of the funeral as possible. The applicant may delegate inspection to a nominee or be accompanied by someone. You should make every effort to ensure that the applicant can inspect the forms in private although we appreciate that it may not always be easy to find a suitable place.

5. The applicant should not be charged a fee to inspect the forms. However, if he or she wants a medical explanation for the cause of death they should be advised that the medical referee may charge a fee for this (that is entirely a matter for the medical referee).

On the other hand, if the applicant wishes to draw the medical referee's attention to an (alleged) inconsistency or inaccuracy within the medical forms then there should be no charge for so doing. Cases where the cause of death is not considered by the medical referee to be natural need to be referred to the local coroner for further consideration.

6. The inspection should take place at least 24 hours before the funeral is due to take place in order that any further investigation or clarification is carried out by the medical referee or others. The family may wish that the funeral service go ahead but that the cremation is deferred in case the coroner wishes the body to be examined. In such cases it will be necessary for the body to be returned to the funeral directors pending any final decision by the coroner. We anticipate that cases like these will be extremely rare.

7. We do not expect there will be great demand for inspection, given that the more 'difficult' cases will have already been referred to the coroner for investigation, and that the vast majority of families have no concerns with the death. Regulation 32 requires the registrar of each cremation authority to keep a register of cremations and one of the particulars that is required to be kept is the name and address of any person who exercises the new right to inspect the medical certificates. As we shall be reviewing the operation of the new right it would also be very helpful if you would send us details of the cases where the forms have been inspected.

Form Cremation 2 – Application for Cremation of Body Parts (replacing form AA)

8. There is no right to inspect the associated certificate releasing body parts for cremation (form Cremation 8) because it provides no information about the cause of death and the body will have already been cremated or buried.

Form Cremation 3 – Application for Cremation of Stillborn Baby

9. You should ensure that the form Cremation 3 is either accompanied by a form Cremation 9 (certificate of stillbirth) or by a declaration given by a person who can give information concerning the birth (see regulation 20(2)). Where the stillbirth took place outside England and Wales, a broadly equivalent form to form Cremation 9 can be given (please refer to regulation 14(4)). There is no right to inspect the certificate of stillbirth as there is no cause of death.

Form Cremation 4 – Medical Certificate (replacing form B)

10. You should ensure that all questions have been answered before passing the forms to the medical referee. All doctors must be fully registered with the General Medical Council (GMC).

Form Cremation 5 – Confirmatory Medical Certificate (replacing form C)

11. Medical referees have been given information about the eligibility of doctors from the European Economic Area (EEA) whose periods of qualification before full registration with the GMC may count towards the five-year period and is attached at **Annex B**. It is very important that doctors from outside the EEA and with less than five years' full registration do not sign form Cremation 5. You should reject forms completed by such doctors and advise the funeral director so that any fees paid can be refunded or transferred to a suitably qualified doctor.

Form Cremation 6 – Certificate of Coroner (replacing form E)

12. The space for the cause of death to be recorded should not be left blank (even if the cause is unascertained).

Form Cremation 7 – Certificate following Anatomical Examination (replacing form H)

13. The form refers to licences granted under the Human Tissue Act 2004 but it can be adapted to deal with older anatomical remains where disposal of the body has been delayed.

Form Cremation 8 – Certificate releasing Body Parts for Cremation (replacing form DD)

14. The body parts must belong to a named person. Anonymous material should be incinerated.

Form Cremation 9 – Certificate of Stillbirth

15. This form should be linked with form Cremation 3 and the appropriate registration document. If the medical referee if satisfied that cremation can take place, he or she will authorise it on form Cremation 13. The form may be completed by a registered midwife as well as by a fully registered medical practitioner.

Form Cremation 10 – Authorisation of Cremation of Deceased Person by Medical Referee (replacing form F)

16. The medical referee will authorise cremation of a deceased person after he or she is satisfied by the information on form Cremation 1, form Cremation 4, form Cremation 5, form Cremation 6 or form Cremation 7 as well as the registration document where registration is required before cremation can take place (this will not be necessary in cases involving the coroner).

17. If the applicant or the applicant's nominee has asked to inspect the medical forms you may wish to advise the medical referee. However, if the applicant or nominee has no concerns to raise with the medical referee or does not wish to seek advice from the referee there is no overwhelming need to do so. If the applicant or nominee has made it clear to staff at the crematorium that they wish to raise matters of concern with a coroner authorisation of the cremation should not take place until these have been resolved. You will need to be in close liaison with the funeral directors and the coroner's office while the situation remains unresolved.

Form Cremation 12 – Authorisation of Cremation of Body Parts by Medical Referee (replacing form FF)

18. The medical referee will only authorise cremation after consideration of a form Cremation 2 and form Cremation 8 and the appropriate registration documentation.

Form Cremation 13 – Authorisation of Cremation of Remains of Stillborn Child by Medical Referee

19. The medical referee will only authorise cremation of a stillborn baby after having considered forms Cremation 3 and either Cremation 9 (or the overseas equivalent) or a declaration given by a person who can give information concerning the birth and the appropriate registration document.

Form Cremation 11 – Certificate after Post-Mortem Examination

20. You will need to decide whether you or the family will pay for any post-mortem examination ordered by the medical referee and that all the relevant provisions of the Human Tissue Act 2004 are met. These include any necessary consent from the applicant or other family member for the post-mortem examination to take place, that the pathologist is duly licensed by the Human Tissue Authority 2004 and that the place where the post-mortem is to take place is also duly licensed.

Further information

21. This guidance is not exhaustive. If you have any further queries or need further information about the new regulations please contact Brian Patterson on 020 3334 6404 (brian.patterson@justice.gsi.gov.uk).

Annex B

European Economic Area

European Union Members: Universities where Primary European Qualifications can be obtained within each state

Austria – Graz, Innsbruck, Salzburg, Salzburg (Paracelsus), Vienna (Wien)

Belgium – Antwerp, Brussels, Diepenbeek (Limburg), Gent, Louvain (Leuven), Liege, Mons, Namur

Bulgaria – Pleven, Plovdiv, Sofia, Trakia (Thrace), Varna

Cyprus – Medical Council of Cyprus (equivalent to General Medical Council)

Czech Republic – Brno (Masaryk Univ.), Hradec Kralove, Pilsen, Prague (Charles University), Olomouc

Denmark – Aarhus, Copenhagen, Syddansk (Odense)

Estonia – Tartu

Finland – Helsinki, Kuopio, Oulu, Tampere, Turku

France – Aix-Marseille, Amiens (Jules Verne), Angers, Besançon (Franche-Comté), Bordeaux (Victor Segalen), Brest (Bretagne), Caen, Clermont-Ferrand (Auvergne), Dijon, Grenoble, Univ Scientifique et Medicale Grenoble, Lille, Henri Warembourg de Lille, Limoges, Lyon-Sud, Lyon (Univ Claude-Bernard), Lyon (Alexis-Carrel), Montpellier-Nimes, Nancy, Nantes, Nice, Paris (Denis Diderot), Paris (Pierre et Marie Curie), Paris (René Descartes), Paris-Sud, Paris Val de Marne (Creteil), Poitiers, Reims, Rennes, Rouen,St Etienne, Strasbourg, Toulouse, Tours

Germany – Aachen, Berlin (Freiuniversität), Berlin (Humboldt), Bochum, Bonn, Dresden, Düsseldorf, Erlangen-Nürnberg, Essen, Frankfurt-am-Main, Freiburg im Breisgau, Giessen, Göttingen, Greifswald, Halle/Wittenberg, Hamburg, Hannover, Heidelberg, Homburg, Jena, Kiel, Köln (Cologne), Leipzig, Lübeck, Magdeburg, Mainz, Mannheim, Marburg, München (Ludwig-Maximilians), München (Technische), Münster, Regensburg, Rostock, Ulm, Witten-Herdecke, Tübingen, Würzburg

Greece – Alexandroupolis (Thrace), Athens (National), Crete, Ioannina, Patras, Larissa (Thessaly) Thessaloniki

Hungary – Semmelweis/Budapest, Debrecen, Pécs, Szeged

Iceland – Reykjavik

Ireland – Cork, Dublin (RCS), University College Dublin, Galway,

Italy – Ancona, Bari, Bologna, Brescia, Cagliari, Catania, Catanzaro (Reggio-Calabria), Chieti (D'Annunzio), Ferrara, Firenze, Genova, Messina, Milano, Modena, Napoli, Napoli (Federico II), Padova, Palermo, Parma, Pavia, Perugia, Pisa, Roma, Rome (Campus Bio-Medico), Sassari, Siena, Torino, Trieste, Udine, Varese, Verona

Latvia – Riga (Stradins), University of Latvia (Riga)

Liechtenstein – Nil

Lithuania – Kaunas, Vilnius

Luxembourg – Nil

Malta – Univ of Malta (Msida)

Netherlands – Amsterdam, Amsterdam (Vrije) Groningen, Leiden, Maastricht, Nijmegen, Rotterdam (Erasmus), Utrecht

Norway – Bergen, Oslo, Tromsø, Trondheim

Poland – Bialystok, Bydgoszcz, Gdansk, Krakow (Jagiellonian), Lodz (Military), Lublin, Poznan, Szczecin, Warsaw (Academy and Postgraduate), Wroclaw

Portugal – Beira, Coimbra, Lisbon, Porto (Abel Salazar) Porto

Romania – Arad, Brasov, Bucharest, Cluj-Napoca, Constanta, Craiova, Iasi, Muras, Oradea, Sibiu, Targu Timisoara

Slovakia – Bratislava, Kosice

Slovenia – Ljubljana

Spain – Albacete (Castillo la Mancha), Alcalá, Alicante, Badajoz (Extremadura), Barcelona, Barcelona (Autonoma), Barcelona (Pompeu Fabra), Cádiz, Córdoba, Granada, La Laguna Las Palmas de Gran Canaria, Lleida, Madrid (San Pablo), Madrid (Autonoma), Madrid (Complutense), Málaga Murcia, Pamplona (Navarra), Oviedo, Reus (Tarragona/Rovira Virgili) Salamanca, San Sebastian (Pais Vasco), Santa Cruz de Tenerife, Santander (Cantabria), Sevilla, Tenerife, Valencia, Valladolid, Zaragosa

Sweden – Göteborg, Linköping, Lund, Stockholm (Karolinska), Umeä, Uppsala

Switzerland* – Basel, Bern, Genève, Lausanne, Zürich

United Kingdom – five years' registration required wherever qualified

*Swiss nationals benefit from EC freedom of movement legislation.

Cremation Regulations 2008

Guidance for doctors

3 November 2008

Contents

Summary of guidance	2
Introduction	4
Those who can sign forms Cremation 4 and Cremation 5 – Overseas Doctors	4
Corroboration of cause of death – deaths in hospital	6
Dentists	7
Completion of forms Cremation 4 and 5	7
Right of inspection	8
Form Cremation 4 – Medical Certificate	8
Form Cremation 5 – Confirmatory Medical Certificate	10
Requirement for form Cremation 5	10
Causes of death – old age	11
Deaths abroad	12
Body parts	12
Unidentified remains	12
Cremation of non-viable foetal remains	12
Annex A: European Economic Area and locations of institutions awarding primary medical qualifications	13

Summary – please read the full guidance carefully

- You must answer **all the questions** on the forms.
- The form Cremation 5 doctor should always properly check Form Cremation 4 – it is your responsibility to check thoroughly both forms and to query any inconsistencies.
- The medical referee is likely to reject **illegible forms**.
- We expect the doctor signing form Cremation 4 to have treated the deceased during the last illness and to have normally seen the deceased within 14 days of death.
- **Modes of death**, e.g. 'multi organ failure' or 'heart attack' are unacceptable as a cause of death; the medical referee is likely to reject forms without a proper cause of death.
- **'Old age'** as a standalone cause of death for over 80s is acceptable for registration purposes, but medical referees have been advised to exercise caution if 'old age' is given as a cause of death and may well make further enquiries.
- You should complete the **forms as soon as possible**: delays to funerals are unfair to bereaved families.
- **Form Cremation 5 doctors** must be registered medical practitioners for at least five years and, if paragraph 10 of Schedule 1 to the Medical Act 1983 (Amendment) Order 2002 (S.I. 2002/3135) is in force, hold a licence to practise.
- Up-to-date information about the qualifications of European doctors is on the General Medical Council's website – see also **Annex A** of this guidance.
- The form Cremation 5 doctor cannot be a partner or work colleague of the form Cremation 4 doctor or a relative of the deceased; the two doctors must be truly independent of one another, i.e. not on the same team in hospital or a locum at the same surgery.
- It is expected that at least one of questions 2 to 5 of form Cremation 5 will be answered in the affirmative.

General

- Medical referees are unable to authorise a cremation **unless the relevant forms have been properly completed in accordance with the regulations.**

- Medical referees have the statutory power to reject incompletely completed forms and may refuse to authorise cremation until the forms are completed to their satisfaction.

- Medical referees also have the power to make any enquiry they may consider necessary about an application or certificate.

- You should assist medical referees in the discharge of their duties by completing the cremation certificates fully and accurately, and by responding to any further enquiries as helpfully as possible.

- Forms Cremation 4 and Cremation 5 do not need to be completed where the application relates to the cremation of body parts, to a stillborn child or to the exhumed remains of a deceased person who has already been buried for a period of one year or more.

Introduction

1. This guidance provides advice to doctors who complete certificates in connection with applications for cremation. It complements advice provided to crematoria medical referees. The main aim is to ensure that medical practitioners are aware of and meet the requirements of the regulations and avoid unnecessary delay to funerals.

2. Forms Cremation 4 and Cremation 5 are available on our website www.justice.gov.uk. You may be asked to complete forms which have been 'personalised' for each crematorium, including marginal explanatory notes. Forms which do not comply with the statutory requirements are not valid. If you have any doubts about the forms you should check with the crematorium manager. The forms made under the previous 1930 regulations may be used until 31 January 2009.

Those who can sign forms Cremation 4 and Cremation 5 – overseas doctors

3. Regulation 17 of the Cremation Regulations 2008 requires the confirmatory medical certificate (form Cremation 5) to be completed by a registered medical practitioner of at least five years' standing. This means a registered medical practitioner who has been fully registered under the Medical Act 1983 for at least five years and, if paragraph 10 of Schedule 1 to the Medical Act 1983 (Amendment) Order 2002 has come into force, who has held a licence to practice under that Act for at least five years or since that paragraph came into force.

4. So far as overseas doctors are concerned, European Economic Area (EEA) member states must recognise one another's diplomas in medicine, subject to certain standards being fulfilled. A list of 'primary European qualifications' which are recognised in the UK in accordance with EC Directive 2005/36/EC is set out in Schedule 1 to the European Primary Medical Qualification Regulations 1996. Schedule 1 to these regulations contains a list of amendments to Schedule 2 to the Medical Act 1983. At that time this Schedule to the Act contained a list of primary European qualifications.

Primary European qualifications are no longer described in this way and Schedule 2 to the Medical Act 1983 was revoked on 3 December 2007 by the European Qualifications (Health and Social Care Professions) Regulations 2007 (Regulation 31).

5. Unlike previous Directives, the current Directive extends the principle of mutual recognition of professional qualifications to those awarded outside the EEA if the holder of a 'third country' qualification is an exempt person (i.e. a national of a relevant European state or entitled to be treated as such) and has three years' professional experience in the profession concerned on the territory of the relevant European state that initially recognised the qualification. A list of the EEA member states and the places where primary medical qualifications are granted is given at **Annex A**. It follows that a **national of any EEA member state** holding a primary European qualification is entitled to be registered in the UK as a fully registered medical practitioner and experience acquired under the primary European qualification outside the UK should be treated as if acquired within the UK. Accordingly, an overseas doctor who has a primary European qualification in an EEA member state will be eligible to sign a cremation form Cremation 5 provided he or she has been registered for five years and holds a licence to practise. The medical register is made up of three lists (as specified in section 30(1) of the Medical Act). Doctors will only be added to the visiting practitioners lists if they obtain registration under the sections of the Act specified (sections 27A, 27B and Schedule 2a).

Corroboration of cause of death – deaths in hospital

6. Regulation 17 also requires that the registered medical practitioner who completes the confirmatory medical certificate should not be a relative of the deceased, or a relative or partner or colleague in the same practice or clinical team of the doctor who has given the cremation certificate in form Cremation 4.

7. The reason for this is to provide corroboration of the medical circumstances in which death took place. Medical referees will need to be satisfied that the doctors who complete forms Cremation 4 and Cremation 5 are sufficiently independent of each other in all cases.

8. Similarly, where a junior hospital doctor has completed the certificate in form Cremation 4, the doctor who signs the form Cremation 5 should not have been in charge of the case, nor directly concerned in the patient's treatment. The deceased's GP should not complete form Cremation 5 (this includes where the deceased has been resident in a care home if the GP had treated the deceased at some stage).

You should be aware that criminal and General Medical Council proceedings have been successfully brought against doctors who have falsely completed the forms.

Dentists

9. Dentists are not qualified to sign cremation certificates.

Completion of forms Cremation 4 (Medical Certificate) and Cremation 5 (Confirmatory Medical Certificate) (replacing forms B and C)

10. The most frequently occurring errors in completion these forms are:

(a) failure to complete **all** questions in full

(b) deletion of questions

(c) incorrect completion of forms

(d) illegible handwriting

(e) discrepancies between the forms as to the date and time of death.

11. Abbreviations for causes of death are unacceptable where the abbreviation is unclear, unusual or ambiguous; in such cases, the medical referee is likely to make further enquiries of you. You should sign the form. The signatures cannot be an abbreviation or a stamp.

12. You must complete the form yourself. It must not be completed by another person on your behalf. The form Cremation 5 doctor should not amend form Cremation 4, but instead record any differences (e.g. as to the cause of death) on his or her own form.

13. Medical referees will expect that the evidence offered on the certificates demonstrates sound clinical grounds for the cause of death given, and you should complete form Cremation 4 with this in mind.

Right of inspection

14. When you complete form Cremation 4 or Cremation 5 you should be aware that the applicant for cremation has a new right to inspect these forms. **Some of the information which is requested by the forms (in particular, questions 9 and 12 on form Cremation 4) may have been given to you by the deceased in confidence. If it is included in the form it may be disclosed to the applicant for cremation if they chose to inspect the form. If this would be a breach of confidence you may give the information to the medical referee on a separate sheet of paper attached to the form explaining your reasons for this and that the information should not be disclosed.** It is therefore important that you bear this in mind when you complete the forms. You should also ensure that your handwriting is legible.

15. The following paragraphs address some other common issues.

Form Cremation 4 – Medical Certificate

Question 5: 'usual medical attendant'

16. The usual medical attendant is normally taken to be the deceased's GP. Where the deceased has been an in-patient in hospital for a short period of time, that is less than 24 hours, it may be better to regard the patient's GP as the usual medical attendant, rather than the hospital doctor who attended him or her. (See also paragraph 8 above.) It is appreciated that many patients in hospital are treated by a number of doctors.

Question 6: 'how long you attended the deceased during their last illness?'

17. To complete form Cremation 4 you should have attended the deceased during their last illness. In the primary care setting, a demonstrable prior period of care or the presence of the certifying doctor at the death will usually be enough. In exceptional circumstances, a general practitioner partner may be acceptable if he or she had seen the deceased outside the normally acceptable

period (14 days) and the attending partner is unavailable although in such cases there will usually have been consultation with a coroner.

18. The minimum period of hospital care sufficient to meet the requirement should normally be 24 hours. When the period is less than 24 hours you must inform a coroner.

Question 7: 'the number of days and hours before the deceased's death that you saw them alive'

19. The normal expectation is that you will have seen the deceased during the course of the last illness within 14 days before death; otherwise you should refer the death to a coroner.

Question 9: symptoms and other conditions

20. You should complete this box with your observations of the deceased's symptoms etc. in the period leading up to death.

Question 10: hospital post-mortem examination

21. If a non-coronial hospital post-mortem examination, i.e. one requiring consent, has been carried out or supervised either by you or by someone with the necessary five years' period of full registration, you should indicate this here and the cause of death in Question 11 should be the findings of the examination. In these cases form Cremation 5 (the Confirmatory Medical Certificate) is not required.

Question 11: cause of death

22. The cause of death should normally be that set out on the medical certificate of the cause of death sent to the Registrar of Deaths. Your answer should indicate when this has been informed by other sources, e.g. patient history, operative procedures or medical or lay witnesses.

Questions 12 and 13: operations

23. You should refer any operation which may have shortened the life of the deceased to a coroner for consideration and possible investigation.

Questions 14, 15 and 16: those nursing the deceased or present at death

24. The doctor completing form Cremation 5 must be able to contact the people you name. Therefore you must give full names and contact details.

Questions 20 and 21: referral to coroner/coroner's office

25. You are asked to ensure that a coroner is notified if any suspicious circumstances come to your attention. In cases where either of the form Cremation 4 or form Cremation 5 doctors has consulted a coroner but the coroner does not consider that his or her involvement is necessary, this should be recorded by the medical practitioner concerned.

Question 23: implants

26. Some implants cause a serious health and safety risk at the crematorium and must be removed.

Form Cremation 5 – Confirmatory Medical Certificate

Requirement for form Cremation 5

27. Form Cremation 5 is not required where the death occurred in hospital, the deceased was an in-patient there, and a post-mortem has been carried out or supervised by a registered medical practitioner of at least five years' standing who is not a relative of the deceased, or a relative, partner or colleague in the same practice or clinical team of the medical practitioner giving form Cremation 4, and the medical attendant giving form Cremation 4 knows the results of the examination.

28. If form Cremation 5 has been completed where there is no need to do so, any fee paid should be refunded to the applicant.

29. The cause of death on the form Cremation 5 does not need to be the same as the one given on the form Cremation 4, but you should explain any discrepancy.

30. We consider that, with the exception of Questions 6 and 7, you should answer in the **affirmative** all the questions in Part 2 in all but the most extreme circumstances (e.g. if the form Cremation 4 doctor is taken seriously ill, for example). Nevertheless, Question 2 should be answered in the affirmative **only if** you have seen and questioned a medical practitioner **other than** the form Cremation doctor.

Question 1: 'have you questioned the medical practitioner?'

31. If you have not seen or spoken to the form Cremation 4 doctor, you should only complete form Cremation 5 to show that the enquiries have been 'adequate'. This should only be necessary in the most exceptional circumstances, for example when the form Cremation 4 doctor has fallen seriously ill.

32. Medical referees will expect that the evidence offered on the certificates demonstrates sound clinical grounds for the cause of death given, and you should complete form Cremation 5 with this in mind.

Causes of death – old age

33. The General Register Office advises that in certain circumstances and if the deceased is older than 80 years of age 'old age' may be an acceptable cause of death on medical certificates. 'Old age' alone, however, is unlikely to be an acceptable cause of death for cremation purposes, as the medical referee must be satisfied that the cause of death has been definitely ascertained. 'Old age' is commonly given as a cause of death where the deceased has been suffering from a number of conditions leading to death but it has not been possible to decide which particular condition led to the death. We cannot offer substantive guidance on a matter which must ultimately be a clinical decision for you. However, medical referees must be satisfied that 'old age' is an appropriate cause of death in all the circumstances. It cannot be used where the cause of death is properly 'unascertained' and which should on that account be referred to a coroner.

Deaths abroad

34. Where someone dies abroad and the body is repatriated to England or Wales for cremation, it is unlikely that you will be in a position to complete forms Cremation 4 or Cremation 5. An application for cremation may be made if a coroner certifies that no post-mortem examination or inquest is necessary. Enquiries about such cases should be directed to us or to a coroner.

Body parts

35. The cremation of body parts removed following a post-mortem examination will normally only require involvement by pathologists.

Unidentified remains

36. It is highly unlikely that applications for the cremation of unidentified remains will arise without the involvement of a coroner.

Cremation of non-viable foetal remains

37. Foetal remains under 24 weeks of age are not subject to the provisions of the Cremation Act or Regulations, although most crematoria will be prepared to cremate such remains at their discretion. Clearly forms Cremation 4 and Cremation 5 should not be completed.

Annex A

European Economic Area

European Union Members: Universities where Primary European Qualifications can be obtained within each state

Austria – Graz, Innsbruck, Salzburg, Salzburg (Paracelsus), Vienna (Wien)

Belgium – Antwerp, Brussels, Diepenbeek (Limburg), Gent, Louvain (Leuven), Liege, Mons, Namur

Bulgaria – Pleven, Plovdiv, Sofia, Trakia (Thrace), Varna

Ministry of JUSTICE

Cremation Regulations 2008

Guidance for funeral directors

3 November 2008

Contents

The new regulations 2
The forms 2
Annex A 3
Further information 8
Annex B 9
Annex C 11

The new regulations

1. The Cremation Regulations 2008 come into effect on 1 January 2009. They modernise and consolidate all previous regulations, replacing the Cremation Regulations 1930 as amended. A copy of the regulations is attached to this guidance. The forms can be downloaded from our website at www.justice.gov.uk. The forms made under the 1930 Regulations may also be used until 31 January 2009.

2. You should familiarise yourself with the text of the new regulations although there are very few policy changes requiring different procedures. The only significant new provision is that giving the applicant for cremation a right to inspect the medical forms (forms Cremation 4 and Cremation 5) before the medical referee authorises cremation. We expect the numbers of applicants wishing to exercise this right to be relatively low, but we will keep the position under close review.

The forms

3. It is important that the statutory wording is fully adhered to. Medical referees have been instructed to reject forms that do not follow the statutory wording.

4. A minor change to the application form is that the countersignature is no longer required.

5. The forms make it clear that it is a criminal offence under the Cremation Act 1902 wilfully to make a false statement in order to procure a cremation.

6. There are 13 forms which are explained in **Annex A**.

Annex A

Form Cremation 1 - Application for cremation of remains of deceased person (replacing form A)

1. This form is to be completed by the applicant for cremation. This should usually be a near relative or an executor. If the applicant is not a near relative or an executor reasons should be given on the form explaining why that person is making the application rather than a near relative or an executor. All questions will need to be answered. All parts of the form have to be completed before it is passed to the medical referee. You should assist applicants in providing the information which is required.

2. Question 10 asks about hazardous implants. The medical referee will need to check the information provided with that given by the certifying doctor. After discussion with the applicant, you may also be able to provide information or confirm that the implant has been removed.

3. Part 5 of the form deals with the applicant's **right to inspect** the medical forms (forms Cremation 4 and Cremation 5) before the medical referee authorises cremation. We expect you to advise the applicant in neutral terms of the right and neither to encourage nor deter applicants from exercising it (a suggested form of words is set out at **Annex B**). In certain circumstances, the death may need to be referred to a coroner. The coroner may then require a post-mortem examination to be held or an inquest to be opened. In these circumstances there is no right of inspection, as there are no medical forms to inspect and the death is being fully investigated.

4. You should ensure that forms Cremation 1, 4 and 5 are sent to the crematorium as soon as possible before the date of the funeral. This is to ensure that the funeral is not delayed in the event that the applicant wants to inspect the forms. The applicant may not, however, want to inspect the forms if he or she would like the funeral to take place as soon after death as possible.

5. There is no easy solution to reconciling the applicant's right of inspection with a timely funeral. Your main role is to ensure that the forms are completed as quickly as possible, to facilitate inspection, and - importantly - to keep in contact with all the parties concerned in the process. If the applicant says that they want to see the forms you will need to advise them that they may delegate inspection to a nominee or that they may be accompanied. Space at crematorium offices is sometimes short and we appreciate that it may not always be easy to identify a suitable place for the applicant to inspect the forms. [It may be acceptable for the applicant to inspect the forms at your office, but that should only be with the agreement of the cremation authority.]

6. We have advised cremation authorities that we do not expect the applicant to be charged a separate fee for inspecting the forms. However, if the applicant wants a medical explanation for the cause of death you should advise him or her that the medical referee may charge a fee for doing this (that is entirely a matter for the medical referee). On the other hand, if the applicant wishes to draw the medical referee's attention to a possible inconsistency or inaccuracy within the medical forms, we do not think that there should be a charge for so doing.

7. If the applicant's inspection of the forms raises a possibility that the cause of death was not natural, the medical referee may consider that the case should be referred to a coroner for further consideration. Any assistance that you can provide in ensuring that the referral takes place as smoothly and speedily as possible will be welcomed.

8. The forms must be inspected at least 24 hours before the funeral is due to take place, to enable any further investigation or clarification to be carried out by the medical referee or others. The family may want the funeral to go ahead but cremation to be deferred, in case the coroner wants the body to be examined. In such cases it will be necessary for the body to be returned to your premises pending any final decision by the coroner. We anticipate that cases like these will be extremely rare.

9. We do not expect there will be great demand for inspection, given that the more 'difficult' cases will have already been referred to the coroner for investigation and most applicants do not have concerns about the circumstances surrounding the death.

Form Cremation 2 - Application for cremation of body parts (replacing form AA)

10. This form should also be completed by a near relative or an executor. If it is more appropriate for the form to be completed by someone acting on behalf of the next of kin (perhaps the bereavement officer at the hospital) then an explanation for this should be given on the form. There is no right to inspect the associated certificate releasing body parts for cremation (form Cremation 8), because it provides no information about the cause of death and the body will have already been cremated or buried. Applications for the cremation of body parts are likely to remain as infrequent as under the previous regulations.

Form Cremation 3 - Application for cremation of stillborn baby

11. This form may be completed by one of the parents of the stillborn baby but may also be completed by the bereavement officer at the hospital. There is no right to inspect the associated certificate of stillbirth (form Cremation 9), as there is no cause of death. You should ensure that form Cremation 3 is either accompanied by form Cremation 9 or by a declaration given by a person who can give information concerning the birth (see regulation 20(2)). Where the stillbirth took place outside England and Wales, a broadly equivalent form to form Cremation 9 can be given (please refer to regulation 14(4)).

Form Cremation 4 - Medical certificate (replacing form B)

12. This form will need to be completed by a doctor who can certify the cause of death. It contains the most detailed information about the circumstances surrounding the death. All questions should be answered. The doctor completing the form will need to give information as to whether any hazardous implant has been removed and whether the death has been discussed with a coroner.

Form Cremation 5 - Confirmatory medical certificate (replacing form C)

13. Medical referees have been given information about the eligibility of doctors from the European Economic Area (EEA) whose periods of qualification before full registration with the General Medical Council may count towards the five-year period. It is attached at **Annex C**. It is very important that doctors from outside the EEA and with less than five years full registration do not sign form Cremation 5. Medical referees should inform you that they have rejected such forms, so that you can refund any fee the doctor concerned may have been paid.

Form Cremation 6 - Certificate of coroner (replacing form E)

14. Please note that there is a space for the cause of death to be recorded. This should not be left blank (even if the cause is unascertained).

Form Cremation 7 - Certificate following anatomical examination (replacing form H)

Form Cremation 8 - Certificate releasing body parts for cremation (replacing form DD)

Form Cremation 9 - Certificate of stillbirth

15. This form should be linked with form Cremation 3 and the appropriate registration document. If the medical referee is satisfied that cremation can take place, he or she will authorise it with form Cremation 13. The form may be completed by a registered midwife as well as by a fully registered medical practitioner.

Form Cremation 10 - Authorisation of cremation of deceased person by medical referee (replacing form F)

Form Cremation 11 - Certificate after post-mortem examination (replacing form D)

16. Cremation authorities will need to decide who should pay for any post-mortem examination ordered by the medical referee and that all the relevant provisions of the Human Tissue Act 2004 are met. These include any necessary consent from the applicant or other family member for the post-mortem examination to take place, that the post-mortem is made by a pathologist under the authority of a licence issued for that purpose by the Human Tissue Authority, and that the place where the post-mortem is to take place is also duly licensed. You may be asked to assist in obtaining the necessary consent.

Form Cremation 12 - Authorisation of cremation of body parts by medical referee (replacing form FF)

Form Cremation 13 - Authorisation of cremation of remains of stillborn child by medical referee

17. The medical referee will only authorise cremation of a stillborn baby after having considered form Cremation 3 and either form Cremation 9 (or the overseas equivalent) or a declaration given by a person who can give information concerning the birth and the appropriate registration document.

Further information

18. This guidance is not exhaustive. If you have any further queries or need more information about the new regulations please contact Brian Patterson on 020 3334 6404 (brian.patterson@justice.gsi.gov.uk).

Annex B

Suggested form of words to use to explain the right of inspection to applicants

It is essential that you present the right to the applicant in the correct terms. We suggest the following words are used – but only when the death has not been referred to a coroner:

You have the right to inspect the medical forms which doctors complete before cremation is authorised. Cremation is authorised by a medical referee, that is, a doctor whose role it is to check the medical forms.

If you are satisfied that you know the cause of death and have no problems with that cause then you may decide that there is little reason why you need to inspect the forms.

However, if you do have doubts about the cause of death or were surprised that the death happened when it did, you may wish to inspect the forms.

You can inspect the forms yourself or you can nominate someone else to inspect on your behalf. You might want to do this, for example, if you think someone else would be in a better position to go through the forms (perhaps because that person was present at the death and you were not).

You do not have to make up your mind now.

If you already have serious concerns about the death and believe the case should be investigated by a coroner, you need to contact the coroner's office [at this point you should provide contact details and other assistance].

The forms will be available for you to inspect at the crematorium office for no longer than 48 hours after you are informed that they have arrived there.

If you wish, the medical referee can give you advice about the cause of death, but he or she may charge a fee for this service. More information is set out in this leaflet [you should then hand over the leaflet].

If you want the funeral to be held within the next two or three days, it may well be difficult for that to happen and for you also to be able to inspect the medical forms. However, that is your decision.

Annex C

European Economic Area

European Union Members: Universities where Primary European Qualifications can be obtained within each state

Austria – Graz, Innsbruck, Salzburg, Salzburg (Paracelsus), Vienna (Wien)

Belgium – Antwerp, Brussels, Diepenbeek (Limburg), Gent, Louvain (Leuven), Liege, Mons, Namur

Bulgaria – Pleven, Plovdiv, Sofia, Trakia (Thrace), Varna

Cyprus – Medical Council of Cyprus (equivalent to General Medical Council)

Czech Republic – Brno (Masaryk Univ.), Hradec Kralove, Pilsen, Prague (Charles University), Olomouc

Denmark – Aarhus, Copenhagen, Syddansk (Odense)

About the consent form.....47

Introduction to this Implementation Guide

This *Good practice in consent implementation guide* contains a model consent policy and four consent forms, together with an accompanying information leaflet *About the consent form*. This model documentation has been developed as part of the Department of Health's 'good practice in consent' initiative, as promised in the *NHS Plan,* with the aim of assisting NHS organisations to promote good practice in the way patients are asked to give their consent to treatment, care or research. An electronic version of this documentation can be downloaded from www.doh.gov.uk/consent.

The four forms are designed to meet the needs of different groups of patients at different times:

- consent form 1 for patients able to consent for themselves
- consent form 2 for those with parental responsibility, consenting on behalf of a child/young person
- consent form 3 both for patients able to consent for themselves and for those with parental responsibility consenting on behalf of a child/young person, where the procedure does not involve any impairment of consciousness. This form is shorter than the others, as the fact that the patient is expected to remain alert during the procedure makes some of the information covered in forms 1 and 2 unnecessary. The use of this form is optional.
- consent form 4 for adults who lack capacity to consent to a particular treatment. As no-one else can give consent on behalf of such a patient, they may only be treated if that treatment is believed to be in their 'best interests'. This form requires health professionals to document both how they have come to the conclusion that the patient lacks the capacity to make this particular healthcare decision, and why the proposed treatment would be in the patient's best interests. It also allows the involvement of those close to the patient in making this healthcare decision to be documented.

The development of these forms does not change the current position on *when* written, as opposed to oral, consent to treatment is necessary. It is a matter of local determination what form of consent is appropriate for individual procedures, within the broad guidelines set out in the model consent policy.

Further forms relating to post-mortems and the removal, retention and use of human organs and tissue following post-mortem will be added to this set in due course. A guide to their implementation will be published at the same time.

Customisation of model documentation

Circular HSC 2001/023 makes clear that both consent forms and consent policy should be recognisable across the NHS and that the text included in this implementation guide should not be amended or removed. However, it may be appropriate to customise the documentation to reflect local needs, and the extent to which customisation is acceptable is set out below.

Consent forms

Additional material relevant to local circumstances may be included in consent forms, as long as this does not result in forms becoming too unwieldy or in the font size being reduced inappropriately. NHS trusts who have developed the practice of documenting anaesthetic consent on the main consent form (as opposed to on the anaesthetic record) should feel free to include such a section within their new forms.

Relevant sections of the forms (such as those dealing with benefits and risks) may be pre-printed where high through-put specialties make this feasible and desirable. If this is done, it will, of course, always be necessary for health professionals to consider whether additional risk/benefit information should be added by hand, to reflect the particular needs of the individual patient. It is essential, however, to ensure that this does not lead to a 'conveyor belt' approach to consent in these circumstances.

While consent forms 1 and 2 have been designed in the form of 4 page booklets with the crucial information for patients on the facing inside pages, they may if desired be reduced to 2 sides of a single sheet by making the guidance notes on the back available to health professionals in another way. There must, however, be clear reference on the forms to the availability of those guidance notes, which must be readily accessible. As the guidance notes on consent form 2 (which explain the relatively complicated legal position regarding who may give consent on behalf of a child) may be less familiar to health professionals, it may generally be more appropriate to take this approach for consent form 1 than for consent form 2.

Whatever the format used, a copy of the page documenting the details of the treatment should be offered to the patient, for example through the use of 'no carbon required' (NCR) copies.

The text for patients 'About the consent form' should be made available to patients in advance of their being asked to sign a consent form, and may be published in any appropriate format. Text should only be omitted if it will never be relevant (for example the section on anaesthesia could be omitted if the organisation involved would never be seeking consent for anaesthesia).

Consent policy

The model policy has been designed to encourage the addition of local information where indicated. If it is felt to be helpful to extend the scope of the model policy, this should be done by means of a separate schedule so that it does not affect the existing layout of the rest of the policy. This will enable staff moving between NHS organisations to know exactly where to look for particular information in their new organisation's policy.

Implementation

The required time-scales for implementing the model consent documentation are set out in circular HSC 2001/023. The Clinical Negligence Scheme for Trusts will be revising its consent to treatment standard to reflect the new requirements from the Department of Health and will ensure that Trusts are aware of when they will be assessed against that new standard.

Guidance on consent

The Department has published a range of guidance documents on consent, which are freely available from the NHS Response Line (08701 555 455) or from www.doh.gov.uk/consent. These are listed below:

- *Reference guide to consent for examination or treatment*, March 2001
- *12 key points on consent: the law in England*, March 2001
- *Consent – what you have a right to expect*, July 2001 (leaflet for patients, with versions for adults, children/young people, people with learning disabilities, parents and relatives/carers)

- *Seeking consent: working with children*, November 2001
- *Seeking consent: working with older people*, November 2001
- *Seeking consent: working with people with learning disabilities*, November 2001

Model policy for consent to examination or treatment

1 Introduction

Why consent is crucial

1. Patients have a fundamental legal and ethical right to determine what happens to their own bodies. Valid consent to treatment is therefore absolutely central in all forms of healthcare, from providing personal care to undertaking major surgery. Seeking consent is also a matter of common courtesy between health professionals and patients.

This policy

2. The Department of Health has issued a range of guidance documents on consent (see overleaf), and these should be consulted for details of the law and good practice requirements on consent. This policy sets out the standards and procedures in this [Trust/PCT/PCG/practice] which aim to ensure that health professionals are able to comply with the guidance. While this document is primarily concerned with healthcare, social care colleagues should also be aware of their obligations to obtain consent before providing certain forms of social care, such as those that involve touching the patient or client.

What consent is – and isn't

3. "Consent" is a patient's agreement for a health professional to provide care. Patients may indicate consent non-verbally (for example by presenting their arm for their pulse to be taken), orally, or in writing. For the consent to be valid, the patient must:

    - be competent to take the particular decision;
    - have received sufficient information to take it; and
    - not be acting under duress.

4. The context of consent can take many different forms, ranging from the active request by a patient of a particular treatment (which may or may not be appropriate or available) to the passive acceptance of a health professional's advice. In some cases, the health professional will suggest a particular form of treatment or investigation and after discussion the

patient may agree to accept it. In others, there may be a number of ways of treating a condition, and the health professional will help the patient to decide between them. Some patients, especially those with chronic conditions, become very well informed about their illness and may actively request particular treatments. In many cases, 'seeking consent' is better described as 'joint decision-making': the patient and health professional need to come to an agreement on the best way forward, based on the patient's values and preferences and the health professional's clinical knowledge.

5. Where an adult patient lacks the mental capacity (either temporarily or permanently) to give or withhold consent for themselves, **no-one else can give consent on their behalf**. However, treatment may be given if it is in their best interests, as long as it has not been refused in advance in a valid and applicable advance directive. For further details on advance directives see the Department of Health's *Reference guide to consent for examination or treatment* (chapter 1, paragraph 19).

Guidance on consent

6. The Department of Health has issued a number of guidance documents on consent, and these should be consulted for advice on the current law and good practice requirements in seeking consent. Health professionals must also be aware of any guidance on consent issued by their own regulatory bodies.

    - *Reference guide to consent for examination or treatment* provides a comprehensive summary of the current law on consent, and includes requirements of regulatory bodies such as the General Medical Council where these are more stringent. Copies are available [insert local access details] and may also be accessed on the internet at www.doh.gov.uk/consent.

    - *12 key points on consent: the law in England* has been distributed widely to health professionals working in England. This one-page document summarises those aspects of the law on consent which arise on a daily basis and is attached at Appendix A. Further copies are available from www.doh.gov.uk/consent.

    - Specific guidance, incorporating both the law and good practice advice, is available for health professionals working with children, with people with learning disabilities and with older people. Copies of these booklets are available [insert local details] and on the internet at www.doh.gov.uk/consent.

II Documentation

1. For significant procedures, it is essential for health professionals to document clearly both a patient's agreement to the intervention and the discussions which led up to that agreement. This may be done either through the use of a consent form (with further detail in the patient's notes if necessary), or through documenting in the patient's notes that they have given oral consent.

Written consent

2. Consent is often wrongly equated with a patient's signature on a consent form. A signature on a form is *evidence* that the patient has given consent, but is not *proof* of valid consent. If a patient is rushed into signing a form, on the basis of too little information, the consent may not be valid, despite the signature. Similarly, if a patient has given valid verbal consent, the fact that they are physically unable to sign the form is no bar to treatment. Patients may, if they wish, withdraw consent after they have signed a form: the signature is evidence of the process of consent-giving, not a binding contract.

3. It is rarely a legal requirement to seek written consent,[1] but it is good practice to do so if any of the following circumstances apply:

   - the treatment or procedure is complex, or involves significant risks (the term 'risk' is used throughout to refer to any adverse outcome, including those which some health professionals would describe as 'side-effects' or 'complications')
   - the procedure involves general/regional anaesthesia or sedation
   - providing clinical care is not the primary purpose of the procedure
   - there may be significant consequences for the patient's employment, social or personal life

[1.] The Mental Health Act 1983 and the Human Fertilisation and Embryology Act 1990 require written consent in certain circumstances.

- the treatment is part of a project or programme of research approved by this [Trust/PCT/PCG]

[Individual Trusts/PCTs/PCGs may choose to list in an Annex whether written/oral/non-verbal consent is appropriate for specified procedures.]

4. Completed forms should be kept with the patient's notes. Any changes to a form, made after the form has been signed by the patient, should be initialled and dated by both patient and health professional.

5. It will not usually be necessary to document a patient's consent to routine and low-risk procedures, such as providing personal care or taking a blood sample. However, if you have any reason to believe that the consent may be disputed later or if the procedure is of particular concern to the patient (for example if they have declined, or become very distressed about, similar care in the past), it would be helpful to do so.

Procedures to follow when patients lack capacity to give or withhold consent

6. Where an adult patient does not have the capacity to give or withhold consent to a significant intervention, this fact should be documented in form 4 (form for adults who are unable to consent to investigation or treatment), along with the assessment of the patient's capacity, why the health professional believes the treatment to be in the patient's best interests, and the involvement of people close to the patient. The standard consent forms should never be used for adult patients unable to consent for themselves. For more minor interventions, this information should be entered in the patient's notes.

7. An apparent lack of capacity to give or withhold consent may in fact be the result of communication difficulties rather than genuine incapacity. You should involve appropriate colleagues in making such assessments of incapacity, such as specialist learning disability teams and speech and language therapists, unless the urgency of the patient's situation prevents this. If at all possible, the patient should be assisted to make and communicate their own decision, for example by providing information in non-verbal ways where appropriate.

8. Occasionally, there will not be a consensus on whether a particular treatment is in an incapacitated adult's best interests. Where the consequences of having, or not having, the treatment are potentially serious, a court declaration may be sought. See Appendix D for details of how to do this.

Availability of forms

9. Standard consent forms and forms for adults who are unable to consent for themselves are reproduced in Appendix B and are available from [local details]. There are three versions of the standard consent form: **form 1** for adults or competent children, **form 2** for parental consent for a child or young person and **form 3** for cases where it is envisaged that the patient will remain alert throughout the procedure and no anaesthetist will be involved in their care. The use of form 3 is optional but may be thought more appropriate than form 1 in situations where patients do not need to be made aware of issues surrounding general or regional anaesthesia and do not need to make any advance decisions about additional procedures because they will be in a position to make any such decisions at the time if necessary.

III When should consent be sought?

1. When a patient formally gives their consent to a particular intervention, this is only the *endpoint* of the consent process. It is helpful to see the whole process of information provision, discussion and decision-making as part of 'seeking consent'. This process may take place at one time, or over a series of meetings and discussions, depending on the seriousness of what is proposed and the urgency of the patient's condition.

Single stage process

2. In many cases, it will be appropriate for a health professional to initiate a procedure immediately after discussing it with the patient. For example, during an ongoing episode of care a physiotherapist may suggest a particular manipulative technique and explain how it might help the patient's condition and whether there are any significant risks. If the patient is willing for the technique to be used, they will then give their consent and the procedure can go ahead immediately. In many such cases, consent will be given orally.

3. If a proposed procedure carries significant risks, it will be appropriate to seek written consent, and health professionals must take into consideration whether the patient has had sufficient chance to absorb the information necessary for them to make their decision. As long as it is clear that the patient understands and consents, the health professional may then proceed.

Two or more stage process

4. In most cases where *written* consent is being sought, treatment options will generally be discussed well in advance of the actual procedure being carried out. This may be on just one occasion (either within primary care or in a hospital out-patient clinic), or it might be over a whole series of consultations with a number of different health professionals. The consent process will therefore have at least two stages: the first being the provision of information, discussion of options and initial (oral) decision, and the second being confirmation that the patient still wants to go ahead. The consent form should be used as a means of documenting the information stage(s), as well as the confirmation stage.

5. Patients receiving elective treatment or investigations for which written consent is appropriate should be familiar with the contents of their consent form before they arrive for the actual procedure, and should have received a copy of the page documenting the decision-making process. They may be invited to sign the form, confirming that they wish treatment to go ahead, at any appropriate point before the procedure: in out-patients, at a pre-admission clinic, or when they arrive for treatment. If a form is signed before patients arrive for treatment, however, a member of the healthcare team **must** check with the patient at this point whether they have any further concerns and whether their condition has changed. This is particularly important where there has been a significant lapse of time between the form being signed and the procedure. When confirming the patient's consent and understanding, it is advisable to use a form of words which requires more than a yes/no answer from the patient: for example beginning with "tell me what you're expecting to happen", rather than "is everything all right?"

6. While administrative arrangements will vary, it should always be remembered that for consent to be valid, the patient must feel that it would have been possible for them to refuse, or change their mind. It will rarely be appropriate to ask a patient to sign a consent form after they have begun to be prepared for treatment (for example, by changing into a hospital gown), unless this is unavoidable because of the urgency of the patient's condition.

Seeking consent for anaesthesia

7. Where an anaesthetist is involved in a patient's care, it is their responsibility (not that of a surgeon) to seek consent for anaesthesia, having discussed the benefits and risks. However, in elective treatment it is not acceptable for the patient to receive no information about anaesthesia until their pre-operative visit from the anaesthetist: at such a late stage the patient will not be in a position genuinely to make a decision about whether or not to undergo anaesthesia. Patients should therefore either receive a general leaflet about anaesthesia in out-patients, or have the opportunity to discuss anaesthesia in a pre-assessment clinic. The anaesthetist should ensure that the discussion with the patient and their consent is documented in the anaesthetic record, in the patient's notes or on the consent form. Where the clinician providing the care is personally responsible for anaesthesia (eg where local anaesthesia or sedation is being used), then he or she will also be responsible for ensuring that the patient has given consent to that form of anaesthesia.

8. In addition, where general anaesthesia or sedation is being provided as part of dental treatment, the General Dental Council currently holds dentists responsible for ensuring that the patient has all the necessary information. In such cases, the anaesthetist and dentist will therefore share that responsibility.

Emergencies

9. Clearly in emergencies, the two stages (discussion of options and confirmation that the patient wishes to go ahead) will follow straight on from each other, and it may often be appropriate to use the patient's notes to document any discussion and the patient's consent, rather than using a form. The urgency of the patient's situation may limit the quantity of information that they can be given, but should not affect its quality.

Treatment of young children

10. When babies or young children are being cared for in hospital, it will not usually seem practicable to seek their parents' consent on every occasion for every routine intervention such as blood or urine tests or X-rays. However, you should remember that, in law, such consent is required. Where a child is admitted, you should therefore discuss with their parent(s) what routine procedures will be necessary, and ensure that you have their consent for these interventions in advance. If parents specify that they wish to be asked before particular procedures are initiated, you must do so, unless the delay involved in contacting them would put the child's health at risk.

11. Only people with 'parental responsibility' are entitled to give consent on behalf of their children. You must be aware that not all parents have parental responsibility for their children (for example, unmarried fathers do not automatically have such responsibility although they can acquire it). If you are in any doubt about whether the person with the child has parental responsibility for that child, you must check.

IV Provision of information

1. The provision of information is central to the consent process. Before patients can come to a decision about treatment, they need comprehensible information about their condition and about possible treatments/investigations and their risks and benefits (including the risks/benefits of doing nothing). They also need to know whether additional procedures are likely to be necessary as part of the procedure, for example a blood transfusion, or the removal of particular tissue. Once a decision to have a particular treatment/investigation has been made, patients need information about what will happen: where to go, how long they will be in hospital, how they will feel afterwards and so on.

2. Patients and those close to them will vary in how much information they want: from those who want as much detail as possible, including details of rare risks, to those who ask health professionals to make decisions for them. There will always be an element of clinical judgement in determining what information should be given. However, the *presumption* must be that the patient wishes to be well informed about the risks and benefits of the various options. Where the patient makes clear (verbally or non-verbally) that they do not wish to be given this level of information, this should be documented.

3. The following sources of patient information are available in this [Trust/PCT/PCG]:

    - [Insert local details, including advice on accessibility/readability for those developing such materials. Also include what specific provision is made for those who, for reasons of disability or otherwise, would not find printed information particularly accessible (tapes, pictorial materials etc) together with details of local independent advocacy groups where these exist. Some Trusts have developed 'patient passports' determining what information is needed at which points in a patient's 'journey' through healthcare. Others have made provision for patients to receive tape-recordings of consultations so that they have a permanent record of what was discussed.]

Provision for patients whose first language is not English

4. This [Trust/PCT/PCG] is committed to ensuring that patients whose first language is not English receive the information they need and are able to communicate appropriately with healthcare staff. It is not appropriate to use children to interpret for family members who do not speak English.

    - [Insert local details of how to access translation and interpreting service, what materials are available in which languages etc. Reference other relevant local policies or guidance eg on use of interpreting. Helpful guidance is found in the toolkit *Bridging the Gap* produced by Sheffield Health Authority and the Commission for Racial Equality.[2]]

Access to more detailed or specialist information

5. Patients may sometimes request more detailed information about their condition or about a proposed treatment than that provided in general leaflets. This [Trust/PCT/PCG] has made the following arrangements to assist patients to obtain such information:

    - [Insert local details eg help via PALS, access on site to NHS Direct Online and the National Electronic Library for Health, links with local medical libraries. In hospitals, this policy can be adapted at Directorate level to include more specific information here.]

Access to health professionals between formal appointments

6. After an appointment with a health professional in primary care or in out-patients, patients will often think of further questions which they would like answered before they take their decision. Where possible, it will be much quicker and easier for the patient to contact the healthcare team by phone than to make another appointment or to wait until the date of an elective procedure (by which time it is too late for the information genuinely to affect the patient's choice). [Insert local details of what systems are in place at GP practice/ Directorate level eg GP surgeries which have a defined hour in the day for phone calls, space in consent form for contact number of appropriate health professional, such as specialist nurse.]

---

2. Contact David Codner (Senior Manager Black and Minority Ethnic Health Issues) at Sheffield Health Authority for details

Open access clinics

7. Where patients access clinics directly, it should not be assumed that their presence at the clinic implies consent to particular treatment. You should ensure that they have the information they need before proceeding with an investigation or treatment. [Insert local details of relevant arrangements, such as provision of information through primary care.]

V Who is responsible for seeking consent?

1. The health professional carrying out the procedure is ultimately responsible for ensuring that the patient is genuinely consenting to what is being done: it is they who will be held responsible in law if this is challenged later.

2. Where oral or non-verbal consent is being sought at the point the procedure will be carried out, this will naturally be done by the health professional responsible. However, team work is a crucial part of the way the NHS operates, and where written consent is being sought it may be appropriate for other members of the team to participate in the process of seeking consent.

Completing consent forms

3. The standard consent form provides space for a health professional to provide information to patients and to sign confirming that they have done so. The health professional providing the information must be competent to do so: either because they themselves carry out the procedure, or because they have received specialist training in advising patients about this procedure, have been assessed, are aware of their own knowledge limitations and are subject to audit.

4. If the patient signs the form in advance of the procedure (for example in out-patients or at a pre-assessment clinic), a health professional involved in their care on the day should sign the form to confirm that the patient still wishes to go ahead and has had any further questions answered. It will be appropriate for any member of the healthcare team (for example a nurse admitting the patient for an elective procedure) to provide the second signature, as long as they have access to appropriate colleagues to answer questions they cannot handle themselves.

   [Insert local details, where appropriate at Directorate level, covering:

   - what training is available for health professionals who do not themselves carry out specific procedures, but could potentially provide the information patients need in coming to a decision.

- what procedures are in place to ensure that the health professionals 'confirming' the patient's consent have genuine access to appropriate colleagues where they are personally not able to answer any remaining questions.]

Responsibility of health professionals

5. It is a health professional's own responsibility:

   - to ensure that when they require colleagues to seek consent on their behalf they are confident that the colleague is competent to do so; and

   - to work within their own competence and not to agree to perform tasks which exceed that competence.

   If you feel that you are being pressurised to seek consent when you do not feel competent to do so [insert local details of whom to contact, such as clinical governance lead.]

VI Refusal of treatment

1. If the process of seeking consent is to be a meaningful one, refusal must be one of the patient's options. A competent adult patient is entitled to refuse any treatment, except in circumstances governed by the *Mental Health Act 1983*. The situation for children is more complex: see the Department of Health's *Seeking consent: working with children* for more detail. The following paragraphs apply primarily to adults.

2. If, after discussion of possible treatment options, a patient refuses all treatment, this fact should be clearly documented in their notes. If the patient has already signed a consent form, but then changes their mind, you (and where possible the patient) should note this on the form.

3. Where a patient has refused a particular intervention, you must ensure that you continue to provide any other appropriate care to which they have consented. You should also ensure that the patient realises they are free to change their mind and accept treatment if they later wish to do so. Where delay may affect their treatment choices, they should be advised accordingly.

4. If a patient consents to a particular procedure but refuses certain aspects of the intervention, you must explain to the patient the possible consequences of their partial refusal. If you genuinely believe that the procedure cannot be safely carried out under the patient's stipulated conditions, you are not obliged to perform it. You must, however, continue to provide any other appropriate care. Where another health professional believes that the treatment can be safely carried out under the conditions specified by the patient, you must on request be prepared to transfer the patient's care to that health professional.

VII Tissue

1. The legal position regarding the use of human tissue (including blood samples and other bodily fluids provided for testing) raises some difficult issues and is currently under review. Such tissue can be very valuable in education and research, and its use may lead to developments in medical knowledge and hence improvements in healthcare for all. At present, this [Trust/PCT/PCG] requires that patients should be given the opportunity to refuse permission for tissue taken from them during surgery or other procedure to be used for education or research purposes. [Insert local details of how this should be done. The system must be well-publicised and transparent, making provision for patients to record their consent or objection to the use of such tissue and for this to be notified to the laboratory. Patients must also be able to record any objections to particular uses or use of particular tissues.]

2. Explicit consent is not necessary for public health surveillance using the unlinked anonymous method, but a well-publicised opt-out policy must apply. [Insert local details.]

3. Pending the outcome of the review of the law governing the use of human organs and tissue, the Department of Health believes that tissue samples may be used for quality assurance purposes without requiring specific patient consent *provided* there is an active policy of informing patients of such use. This is essential to ensure the high quality of service which all patients have the right to expect. Wherever possible, samples of tissue used in this way should be anonymised or pseudonymised. [Insert local details of policy.]

VIII Clinical photography and conventional or digital video recordings

1. Photographic and video recordings made for clinical purposes form part of a patient's record. Although consent to certain recordings, such as X-rays, is implicit in the patient's consent to the procedure, health professionals should always ensure that they make clear in advance if any photographic or video recording will result from that procedure.

2. Photographic and video recordings which are made for treating or assessing a patient must not be used for any purpose other than the patient's care or the audit of that care, without the express consent of the patient or a person with parental responsibility for the patient. The one exception to this principle is set out in paragraph 3 below. If you wish to use such a recording for education, publication or research purposes, you must seek consent in writing, ensuring that the person giving consent is fully aware of the possible uses of the material. In particular, the person must be made aware that you may not be able to control future use of the material once it has been placed in the public domain. If a child is not willing for a recording to be used, you must not use it, even if a person with parental responsibility consents.

3. Photographic and video recordings, made for treating or assessing a patient and from which there is no possibility that the patient might be recognised, may be used within the clinical setting for education or research purposes without express consent from the patient, as long as this policy is well publicised. However, express consent must be sought for any form of publication.

4. If you wish to make a photographic or video recording of a patient specifically for education, publication or research purposes, you must first seek their written consent (or where appropriate that of a person with parental responsibility) to make the recording, and then seek their consent to use it. Patients must know that they are free to stop the recording at any time and that they are entitled to view it if they wish, before deciding whether to give consent to its use. If the patient decides that they are not happy for any recording to be used, it must be destroyed. As with recordings made with therapeutic intent, patients must receive full information on the possible future uses of the recording, including the fact that it may not be possible to withdraw it once it is in the public domain.

5. The situation may sometimes arise where you wish to make a recording specifically for education, publication or research purposes, but the patient is temporarily unable to give or withhold consent because, for example, they are unconscious. In such cases, you may make such a recording, but you must seek consent as soon as the patient regains capacity. You must not use the recording until you have received consent for its use, and if the patient does not consent to any form of use, the recording must be destroyed.

6. If the patient is likely to be permanently unable to give or withhold consent for a recording to be made, you should seek the agreement of some-one close to the patient. You must not make any use of the recording which might be against the interests of the patient. You should also not make, or use, any such recording if the purpose of the recording could equally well be met by recording patients who are able to give or withhold consent.

IX Training

[Insert details of training available on consent in this organisation, covering both basic training on the law of consent, and training on any specific procedures used in this organisation.]

Policy to be reviewed by [date]:

Appendix A

12 key points on consent: the law in England

When do health professionals need consent from patients?

1. Before you examine, treat or care for competent adult patients you must obtain their consent.

2. Adults are always assumed to be competent unless demonstrated otherwise. If you have doubts about their competence, the question to ask is: "can this patient understand and weigh up the information needed to make this decision?" Unexpected decisions do not prove the patient is incompetent, but may indicate a need for further information or explanation.

3. Patients may be competent to make some health care decisions, even if they are not competent to make others.

4. Giving and obtaining consent is usually a process, not a one-off event. Patients can change their minds and withdraw consent at any time. If there is any doubt, you should always check that the patient still consents to your caring for or treating them.

Can children give consent for themselves?

5. Before examining, treating or caring for a child, you must also seek consent. Young people aged 16 and 17 are presumed to have the competence to give consent for themselves. Younger children who understand fully what is involved in the proposed procedure can also give consent (although their parents will ideally be involved). In other cases, some-one with parental responsibility must give consent on the child's behalf, unless they cannot be reached in an emergency. If a competent child consents to treatment, a parent **cannot** over-ride that consent. Legally, a parent can consent if a competent child refuses, but it is likely that taking such a serious step will be rare.

Who is the right person to seek consent?

6. It is always best for the person actually treating the patient to seek the patient's consent. However, you may seek consent on behalf of colleagues if you are capable of performing the procedure in question, or if you have been specially trained to seek consent for that procedure.

What information should be provided?

7. Patients need sufficient information before they can decide whether to give their consent: for example information about the benefits and risks of the proposed treatment, and alternative treatments. If the patient is not offered as much information as they reasonably need to make their decision, and in a form they can understand, their consent may not be valid.

8. Consent must be given voluntarily: not under any form of duress or undue influence from health professionals, family or friends.

Does it matter how the patient gives consent?

9. No: consent can be written, oral or non-verbal. A signature on a consent form does not itself prove the consent is valid – the point of the form is to record the patient's decision, and also increasingly the discussions that have taken place. Your Trust or organisation may have a policy setting out when you need to obtain written consent.

Refusal of treatment

10. Competent adult patients are entitled to refuse treatment, even when it would clearly benefit their health. The only exception to this rule is where the treatment is for a mental disorder and the patient is detained under the Mental Health Act 1983. A competent pregnant woman may refuse any treatment, even if this would be detrimental to the fetus.

Adults who are not competent to give consent

11. **No-one** can give consent on behalf of an incompetent adult. However, you may still treat such a patient if the treatment would be in their best interests. 'Best interests' go wider than best medical interests, to include factors such as the wishes and beliefs of the patient when competent, their current wishes, their general well-being and their spiritual and religious welfare. People close to the patient may be able to give you information on some of these factors. Where the patient has never been competent, relatives, carers and friends may be best placed to advise on the patient's needs and preferences.

12. If an incompetent patient has clearly indicated in the past, while competent, that they would refuse treatment in certain circumstances (an 'advance refusal'), and those circumstances arise, you must abide by that refusal.

This summary cannot cover all situations. For more detail, consult the *Reference guide to consent for examination or treatment*, available from the NHS Response Line 08701 555 455 and at www.doh.gov.uk/consent.

Patient identifier/label

Statement of patient

Please read this form carefully. If your treatment has been planned in advance, you should already have your own copy of page 2 which describes the benefits and risks of the proposed treatment. If not, you will be offered a copy now. If you have any further questions, do ask – we are here to help you. You have the right to change your mind at any time, including after you have signed this form.

I agree to the procedure or course of treatment described on this form.

I understand that you cannot give me a guarantee that a particular person will perform the procedure. The person will, however, have appropriate experience.

I understand that I will have the opportunity to discuss the details of anaesthesia with an anaesthetist before the procedure, unless the urgency of my situation prevents this. (This only applies to patients having general or regional anaesthesia.)

I understand that any procedure in addition to those described on this form will only be carried out if it is necessary to save my life or to prevent serious harm to my health.

I have been told about additional procedures which may become necessary during my treatment. I have listed below any procedures **which I do not wish to be carried out** without further discussion.

_____

_____

☐ Patient has withdrawn consent (ask patient to sign/date here) _____

Guidance to health professionals (to be read in conjunction with consent policy)

What a consent form is for

This form documents the patient's agreement to go ahead with the investigation or treatment you have proposed. It is not a legal waiver – if patients, for example, do not receive enough information on which to base their decision, then the consent may not be valid, even though the form has been signed. Patients are also entitled to change their mind after signing the form, if they retain capacity to do so. The form should act as an aide-memoire to health professionals and patients, by providing a check-list of the kind of information patients should be offered, and by enabling the patient to have a written record of the main points discussed. In no way, however, should the written information provided for the patient be regarded as a substitute for face-to-face discussions with the patient.

The law on consent

See the Department of Health's *Reference guide to consent for examination or treatment* for a comprehensive summary of the law on consent (also available at www.doh.gov.uk/consent).

Who can give consent

Everyone aged 16 or more is presumed to be competent to give consent for themselves, unless the opposite is demonstrated. If a child under the age of 16 has "sufficient understanding and intelligence to enable him or her to understand fully what is proposed", then he or she will be competent to give consent for himself or herself. Young people aged 16 and 17, and legally 'competent' younger children, may therefore sign this form for themselves, but may like a parent to countersign as well. If the child is not able to give consent for himself or herself, some-one with parental responsibility may do so on their behalf and a separate form is available for this purpose. Even where a child is able to give consent for himself or herself, you should always involve those with parental responsibility in the child's care, unless the child specifically asks you not to do so. If a patient is mentally competent to give consent but is physically unable to sign a form, you should complete this form as usual, and ask an independent witness to confirm that the patient has given consent orally or non-verbally.

When NOT to use this form

If the patient is 18 or over and is not legally competent to give consent, you should use form 4 (form for adults who are unable to consent to investigation or treatment) instead of this form. A patient will not be legally competent to give consent if:

- they are unable to comprehend and retain information material to the decision and/or
- they are unable to weigh and use this information in coming to a decision.

You should always take all reasonable steps (for example involving more specialist colleagues) to support a patient in making their own decision, before concluding that they are unable to do so. Relatives **cannot** be asked to sign this form on behalf of an adult who is not legally competent to consent for himself or herself.

Information

Information about what the treatment will involve, its benefits and risks (including side-effects and complications) and the alternatives to the particular procedure proposed, is crucial for patients when making up their minds. The courts have stated that patients should be told about 'significant risks which would affect the judgement of a reasonable patient'. 'Significant' has not been legally defined, but the GMC requires doctors to tell patients about 'serious or frequently occurring' risks. In addition if patients make clear they have particular concerns about certain kinds of risk, you should make sure they are informed about these risks, even if they are very small or rare. You should always answer questions honestly. Sometimes, patients may make it clear that they do not want to have any information about the options, but want you to decide on their behalf. In such circumstances, you should do your best to ensure that the patient receives at least very basic information about what is proposed. Where information is refused, you should document this on page 2 of the form or in the patient's notes.

Guidance to health professionals (to be read in conjunction with consent policy)

This form

This form should be used to document consent to a child's treatment, where that consent is being given by a person with parental responsibility for the child. The term 'parent' has been used in this form as a shorthand for 'person with parental responsibility'. Where children are legally competent to consent for themselves (see below), they may sign the standard 'adult' consent form (form 1). There is space on that form for a parent to countersign if a competent child wishes them to do so.

Who can give consent?

Everyone aged 16 or more is presumed to be competent to give consent for themselves, unless the opposite is demonstrated. The courts have stated that if a child under the age of 16 has "sufficient understanding and intelligence to enable him or her to understand fully what is proposed", then he or she will be competent to give consent for himself or herself. If children are not able to give consent for themselves, some-one with parental responsibility may do so on their behalf.

Although children acquire rights to give consent for themselves as they grow older, people with 'parental responsibility' for a child retain the right to give consent on the child's behalf until the child reaches the age of 18. Therefore, for a number of years, both the child and a person with parental responsibility have the right to give consent to the child's treatment. In law, health professionals only need the consent of one appropriate person before providing treatment. This means that in theory it is lawful to provide treatment to a child under 18 which a person with parental responsibility has authorised, even if the child refuses. As a matter of good practice, however, you should always seek a competent child's consent before providing treatment unless any delay involved in doing so would put the child's life or health at risk. Younger children should also be as involved as possible in decisions about their healthcare. Further advice is given in the Department's guidance *Seeking consent: working with children*. Any differences of opinion between the child and their parents, or between parents, should be clearly documented in the patient's notes.

Parental responsibility

The person(s) with parental responsibility will usually, but not invariably, be the child's birth parents. People with parental responsibility for a child include: the child's mother; the child's father if married to the mother at the child's conception, birth or later; a legally appointed guardian; the local authority if the child is on a care order; or a person named in a residence order in respect of the child. Fathers who have never been married to the child's mother will only have parental responsibility if they have acquired it through a court order or parental responsibility agreement (although this may change in the future).

Information

Information about what the treatment will involve, its benefits and risks (including side-effects and complications) and the alternatives to the particular procedure proposed, is crucial for children and their parents when making up their minds about treatment. The courts have stated that patients should be told about 'significant risks which would affect the judgement of a reasonable patient'. 'Significant' has not been legally defined, but the GMC requires doctors to tell patients about 'serious or frequently occurring' risks. In addition if patients make clear they have particular concerns about certain kinds of risk, you should make sure they are informed about these risks, even if they are very small or rare. You should always answer questions honestly.

Guidance on the law on consent

See the Department of Health publications *Reference guide to consent for examination or treatment* and *Seeking consent: working with children* for a comprehensive summary of the law on consent (also available at www.doh.gov.uk/consent).

Name (PRINT) _____ Job title _____

Statement of interpreter (where appropriate)

I have interpreted the information above to the patient/parent to the best of my ability and in a way in which I believe s/he/they can understand.

Signed _____ Date _____ Name (PRINT) _____

Statement of patient/person with parental responsibility for patient

I agree to the procedure described above.

I understand that you cannot give me a guarantee that a particular person will perform the procedure. The person will, however, have appropriate experience.

I understand that the procedure will/will not involve local anaesthesia.

Signature _____ Date _____

Name (PRINT) _____ Relationship to patient _____

Confirmation of consent (to be completed by a health professional when the patient is admitted for the procedure, if the patient/parent has signed the form in advance)

I have confirmed that the patient/parent has no further questions and wishes the procedure to go ahead.

Signature _____ Date _____

Name (PRINT) _____ Job title _____

Top copy accepted by patient/parent: yes/no (please ring)

Guidance to health professionals (to be read in conjunction with consent policy)

This form

This form documents the patient's agreement (or that of a person with parental responsibility for the patient) to go ahead with the investigation or treatment you have proposed. **It is only designed for procedures where the patient is expected to remain alert throughout and where an anaesthetist is not involved in their care: for example for drug therapy where written consent is deemed appropriate.** In other circumstances you should use either form 1 (for adults/competent children) or form 2 (parental consent for children/young people) as appropriate.

Consent forms are not legal waivers – if patients, for example, do not receive enough information on which to base their decision, then the consent may not be valid, even though the form has been signed. Patients also have every right to change their mind after signing the form.

Who can give consent

Everyone aged 16 or more is presumed to be competent to give consent for themselves, unless the opposite is demonstrated. If a child under the age of 16 has "sufficient understanding and intelligence to enable him or her to understand fully what is proposed", then he or she will be competent to give consent for himself or herself. Young people aged 16 and 17, and legally 'competent' younger children, may therefore sign this form for themselves, if they wish. If the child is not able to give consent for himself or herself, some-one with parental responsibility may do so on their behalf. Even where a child is able to give consent for himself or herself, you should always involve those with parental responsibility in the child's care, unless the child specifically asks you not to do so. If a patient is mentally competent to give consent but is physically unable to sign a form, you should complete this form as usual, and ask an independent witness to confirm that the patient has given consent orally or non-verbally.

When NOT to use this form (see also 'This form' above)

If the patient is 18 or over and is not legally competent to give consent, you should use form 4 (form for adults who are unable to consent to investigation or treatment) instead of this form. A patient will not be legally competent to give consent if:

- they are unable to comprehend and retain information material to the decision and/or
- they are unable to weigh and use this information in coming to a decision.

You should always take all reasonable steps (for example involving more specialist colleagues) to support a patient in making their own decision, before concluding that they are unable to do so. Relatives **cannot** be asked to sign this form on behalf of an adult who is not legally competent to consent for himself or herself.

Information

Information about what the treatment will involve, its benefits and risks (including side-effects and complications) and the alternatives to the particular procedure proposed, is crucial for patients when making up their minds about treatment. The courts have stated that patients should be told about 'significant risks which would affect the judgement of a reasonable patient'. 'Significant' has not been legally defined, but the GMC requires doctors to tell patients about 'serious or frequently occurring' risks. In addition if patients make clear they have particular concerns about certain kinds of risk, you should make sure they are informed about these risks, even if they are very small or rare. You should always answer questions honestly. Sometimes, patients may make it clear that they do not want to have any information about the options, but want you to decide on their behalf. In such circumstances, you should do your best to ensure that the patient receives at least very basic information about what is proposed. Where information is refused, you should document this overleaf or in the patient's notes.

The law on consent

See the Department of Health's *Reference guide to consent for examination or treatment* for a comprehensive summary of the law on consent (also available at www.doh.gov.uk/consent).

[NHS organisation name]

consent form 4

Form for adults who are unable to consent to investigation or treatment

Patient details (or pre-printed label)

Patient's surname/family name _____

Patient's first names _____

Date of birth _____

Responsible health professional _____

Job title _____

NHS number (or other identifier) _____

☐ Male ☐ Female

Special requirements _____
(eg other language/other communication method)

To be retained in patient's notes

Patient identifier/label

All sections to be completed by health professional proposing the procedure

A Details of procedure or course of treatment proposed

(NB see guidance to health professionals overleaf for details of situations where court approval must first be sought)

B Assessment of patient's capacity

I confirm that the patient lacks capacity to give or withhold consent to this procedure or course of treatment because:

☐ the patient is unable to comprehend and retain information material to the decision; and/or
☐ the patient is unable to use and weigh this information in the decision-making process; or
☐ the patient is unconscious

Further details (excluding where patient unconscious): for example how above judgements reached; which colleagues consulted; what attempts made to assist the patient make his or her own decision and why these were not successful.

C Assessment of patient's best interests

To the best of my knowledge, the patient has not refused this procedure in a valid advance directive. Where possible and appropriate, I have consulted with colleagues and those close to the patient, and I believe the procedure to be in the patient's best interests because:

(Where incapacity is likely to be temporary, for example if patient unconscious, or where patient has fluctuating capacity)

The treatment cannot wait until the patient recovers capacity because:

D Involvement of the patient's family and others close to the patient

The final responsibility for determining whether a procedure is in an incapacitated patient's best interests lies with the health professional performing the procedure. However, it is good practice to consult with those close to the patient (eg spouse/partner, family and friends, carer, supporter or advocate) unless you have good reason to believe that the patient would not have wished particular individuals to be consulted, or unless the urgency of their situation prevents this. "Best interests" go far wider than "best medical interests", and include factors such as the patient's wishes and beliefs when competent, their current wishes, their general well-being and their spiritual and religious welfare.

(to be signed by a person or persons close to the patient, if they wish)

I/We have been involved in a discussion with the relevant health professionals over the treatment of (patient's name). I/We understand that he/she is unable to give his/her own consent, based on the criteria set out in this form. I/We also understand that treatment can lawfully be provided if it is in his/her best interests to receive it.

Any other comments (including any concerns about decision)

Name _____ Relationship to patient _____

Address (if not the same as patient) _____

_____

_____

Signature _____ Date _____

If a person close to the patient was not available in person, has this matter been discussed in any other way (eg over the telephone?)

☐ Yes ☐ No

Details:

Signature of health professional proposing treatment

The above procedure is, in my clinical judgement, in the best interests of the patient, who lacks capacity to consent for himself or herself. Where possible and appropriate I have discussed the patient's condition with those close to him or her, and taken their knowledge of the patient's views and beliefs into account in determining his or her best interests.

I have/have not sought a second opinion.

Signature _____ Date _____

Name (PRINT) _____ Job title _____

Where second opinion sought, s/he should sign below to confirm agreement:

Signature _____ Date _____

Name (PRINT) _____ Job title _____

Guidance to health professionals (to be read in conjunction with consent policy)

This form should only be used where it would be usual to seek written consent but an adult patient (18 or over) lacks capacity to give or withhold consent to treatment. If an adult **has** capacity to accept or refuse treatment, you should use the standard consent form and respect any refusal. Where treatment is very urgent (for example if the patient is critically ill), it may not be feasible to fill in a form at the time, but you should document your clinical decisions appropriately afterwards. If treatment is being provided under the authority of Part IV of the *Mental Health Act 1983,* different legal provisions apply and you are required to fill in more specialised forms (although in some circumstances you may find it helpful to use this form as well). If the adult now lacks capacity, but has clearly refused particular treatment in advance of their loss of capacity (for example in an advance directive or 'living will'), then you must abide by that refusal if it was validly made and is applicable to the circumstances. For further information on the law on consent, see the Department of Health's *Reference guide to consent for examination or treatment* (www.doh.gov.uk/consent).

When treatment can be given to a patient who is unable to consent

For treatment to be given to a patient who is unable to consent, the following **must** apply:

- the patient must lack the capacity ('competence') to give or withhold consent to this procedure AND
- the procedure must be in the patient's best interests.

Capacity

A patient will lack capacity to consent to a particular intervention if he or she is:

- unable to comprehend and retain information material to the decision, especially as to the consequences of having, or not having, the intervention in question; and/or
- unable to use and weigh this information in the decision-making process.

Before making a judgement that a patient lacks capacity you must take all steps reasonable in the circumstances to assist the patient in taking their own decisions (this will clearly not apply if the patient is unconscious). This may involve explaining what is involved in very simple language, using pictures and communication and decision-aids as appropriate. People close to the patient (spouse/partner, family, friends and carers) may often be able to help, as may specialist colleagues such as speech and language therapists or learning disability teams, and independent advocates or supporters.

Capacity is 'decision-specific': a patient may lack capacity to take a particular complex decision, but be quite able to take other more straight-forward decisions or parts of decisions.

Best interests

A patient's best interests are not limited to their best medical interests. Other factors which form part of the best interests decision include:

- the wishes and beliefs of the patient when competent
- their current wishes
- their general well-being
- their spiritual and religious welfare

Two incapacitated patients, whose *physical* condition is identical, may therefore have different best interests.

Unless the patient has clearly indicated that particular individuals should not be involved in their care, or unless the urgency of their situation prevents it, you should attempt to involve people close to the patient (spouse/partner, family and friends, carer, supporter or advocate) in the decision-making process. Those close to the patient cannot require you to provide particular treatment which you do not believe to be clinically appropriate. However they will know the patient much better than you do, and therefore are likely to be able to provide valuable information about the patient's wishes and values.

Second opinions and court involvement

Where treatment is complex and/or people close to the patient express doubts about the proposed treatment, a second opinion should be sought, unless the urgency of the patient's condition prevents this. Donation of regenerative tissue such as bone marrow, sterilisation for contraceptive purposes and withdrawal of artificial nutrition or hydration from a patient in PVS must never be undertaken without prior High Court approval. High Court approval can also be sought where there are doubts about the patient's capacity or best interests.

About the consent form

About the consent form

Before a doctor or other health professional examines or treats you, they need your consent. Sometimes you can simply tell them whether you agree with their suggestions. However, sometimes a written record of your decision is helpful – for example if your treatment involves sedation or general anaesthesia. You'll then be asked to sign a consent form. If you later change your mind, you're entitled to withdraw consent – even after signing.

What should I know before deciding?

Health professionals must ensure you know enough to enable you to decide about treatment. They'll write information on the consent form and offer you a copy to keep as well as discussing the choices of treatment with you. Although they may well recommend a particular option, you're free to choose another. People's attitudes vary on things like the amount of risk or pain they're prepared to accept. That goes for the amount of information, too. If you'd rather not know about certain aspects, discuss your worries with whoever is treating you.

Should I ask questions?

Always ask anything you want. As a reminder, you can write your questions in the space over the page. The person you ask should do his or her best to answer, but if they don't know they should find some-one else who is able to discuss your concerns. To support you and prompt questions, you might like to bring a friend or relative. Ask if you'd like someone independent to speak up for you.

Is there anything I should tell people?

If there's any procedure you **don't** want to happen, you should tell the people treating you. It's also important for them to know about any illnesses or allergies which you may have or have suffered from in the past.

Can I find out more about giving consent?

The Department of Health leaflet *Consent – what you have a right to expect* is a detailed guide on consent in versions for adults, children, parents, carers/relatives and people with learning disabilities. Ask for one from your clinic or hospital, order one from the NHS Responseline (08701 555 455) or read it on the web site www.doh.gov.uk/consent.

Who is treating me?

Amongst the health professionals treating you may be a "doctor in training" – medically qualified, but now doing more specialist training. They range from recently qualified doctors to doctors almost ready to be consultants. They will only carry out procedures for which they have been appropriately trained. Someone senior will supervise – either in person accompanying a less experienced doctor in training or available to advise someone more experienced.

What about anaesthesia?

If your treatment involves general or regional anaesthesia (where more than a small part of your body is being anaesthetised), you'll be given general information about it in advance. You'll also have an opportunity to talk with the anaesthetist when he or she assesses your state of health shortly before treatment. Hospitals sometimes have pre-assessment clinics which provide patients with the chance to discuss things a few weeks earlier.

Will samples be taken?

Some kinds of operation involve removing a part of the body (such as a gall bladder or a tooth). You would always be told about this in advance. Other operations may mean taking samples as part of your care. These samples may be of blood or small sections of tissue, for example of an unexplained lump. Such samples may be further checked by other health professionals to ensure the best possible standards. Again, you should be told in advance if samples are likely to be taken.

Sometimes samples taken during operations may also be used for teaching, research or public health monitoring in the future interests of all NHS patients. The NHS trust treating you will have a local system for checking whether you're willing for this to happen.

Photographs and videos

As part of your treatment some kind of photographic record may be made – for example X-rays, clinical photographs or sometimes a video. You will always be told if this is going to happen. The photograph or recording will be kept with your notes and will be held in confidence as part of your medical record. This means that it will normally be seen only by those involved in providing you with care or those who need to check the quality of care you have received. The use of photographs and recordings is also extremely important for other NHS work, such as teaching or medical research. However, we will not use yours in a way that might allow you to be identified or recognised without your express permission.

What if things don't go as expected?

Amongst the 25,000 operations taking place every day, sometimes things don't go as they should. Although the doctor involved should inform you and your family, often the patient is the first to notice something amiss. If you're worried – for example about the after-effects of an operation continuing much longer than you were told to expect – tell a health professional right away. Speak to your GP, or contact your clinic - the phone number should be on your appointment card, letter or consent form copy.

What are the key things to remember?

It's your decision! It's up to you to choose whether or not to consent to what's being proposed. Ask as many questions as you like, and remember to tell the team about anything that concerns you or about any medication, allergies or past history which might affect your general health.

Questions to ask health professionals

As well as giving you information health professionals must listen and do their best to answer your questions. Before your next appointment, you can write some down in the space below.

Questions may be about the **treatment itself**, for example:

- What are the main treatment options?
- What are the benefits of each of the options?
- What are the risks, if any, of each option?
- What are the success rates for different options – nationally, for this unit or for you (the surgeon)?
- Why do you think an operation (if suggested) is necessary?
- What are the risks if I decide to do nothing for the time being?
- How can I expect to feel after the procedure?
- When am I likely to be able to get back to work?

Questions may also be about how the treatment might affect your future state of health or style of life, for example:

- Will I need long-term care?
- Will my mobility be affected?
- Will I still be able to drive?
- Will it affect the kind of work I do?
- Will it affect my personal/sexual relationships?
- Will I be able to take part in my favourite sport/exercises?
- Will I be able to follow my usual diet?

Health care professionals should welcome your views and discuss any issues so they can work in partnership with you for the best outcome.

Cremation Regulations 2008

Guidance for crematorium medical referees

20 September 2010

Contents

Summary of guidance	2
Introduction	4
Act and Regulations	5
Functions	6
Cremation forms – general	8
Those who can sign Forms Cremation 4 and Cremation 5	9
Completion of Forms Cremation 1, Cremation 4 and Cremation 5	11
Other matters	20
Annex A – European Economic Area	22

Summary of guidance

- All questions on Forms Cremation 1, 4 and 5 should be answered.
- You must be satisfied that the applicant is entitled to sign and complete Form Cremation 1.
- It is your responsibility to check forms Cremation 4 and Cremation 5 thoroughly and to query any inconsistencies. Do not assume that the Form Cremation 5 doctor has properly checked Form Cremation 4.
- You should reject illegible forms.
- We consider that Form Cremation 4 should only be completed by a doctor who treated the deceased during the last illness and who had seen him or her within 14 days of death – and not by anyone else on that doctor's behalf. There may be more than one doctor treating a person on a hospital ward – or elsewhere during the last illness. If the main treating doctor has gone on leave or fallen ill it may be possible for another doctor to complete Form Cremation 4.
- Modes of death, e.g. "multi-organ failure" or "heart attack", are unacceptable as a cause of death; you should reject forms which do not have a proper cause of death.
- "Old age" as a stand-alone cause of death for over 80s is acceptable for registration purposes, but you should explore the recent history with the Form Cremation 4 doctor and exercise caution.
- You should not be pressurised into accepting last minute applications; you should, however, be prepared to make yourself available at some stage during each working day.
- If a coroner has completed Form Cremation 6, you still need to check Form Cremation 1 to ensure that the proper person has applied for the cremation.
- If a coroner's office has been made aware of the case but has decided not to issue Form Cremation 6, you must make your own decision on whether to authorise the cremation, liaising with the coroner's office as necessary.
- You may order a post-mortem examination. You will, however, need the permission of the appropriate adult, and it should be made clear who will pay for the post-mortem before you issue instructions.

- You must give written reasons to the applicant if you reject an application.

- You must be satisfied that either a coroner has issued Form Cremation 6, or the death has been registered, or is not required to be registered.

- Form Cremation 5 doctors must be registered medical practitioners for at least 5 years and, if paragraph 10 of Schedule 1 to the Medical Act 1983 (Amendment) Order 2002 (S.I. 2002/3135) is in force, hold a licence to practice.

- Up-to-date information about the qualifications of European doctors is on the General Medical Council's website – see also Annex A.

- The Form Cremation 5 doctor cannot be a partner or colleague in the same practice or clinical team of the Form Cremation 4 doctor, or a relative of the deceased; the two doctors must be truly independent of one another, i.e. not on the same team in hospital or a locum at the same surgery.

Introduction

You should familiarise yourself with the legislation under which you perform your duties. The Cremation Regulations 2008 come into effect on 1 January 2009. Forms 1 to 13 replace and add to forms A to H under previous Regulations. The old forms may still be used for a transitional period of one month, that is until 31 January 2009.

Act and Regulations

The 2008 Regulations ("the Regulations") can be found at www.legislation.gov.uk/uksi/2008/2841/contents/made

Functions

Your functions as medical referee are set out in regulations 23 to 28 of the Cremation Regulations 2008, as follows:

- Not to allow a cremation unless you are satisfied that the death has been properly registered, or is not required to be registered, or that a coroner has issued a certificate as set out in Form Cremation 6;
- To be satisfied that the application and certificates are as required by the Regulations;
- To be satisfied that adequate enquiries have been made by the doctors giving the certificates;
- To be satisfied either that the application has been made by an executor or a near relative of the deceased, or that there is sufficient explanation why the application has not been made by an executor or near relative;
- Not to allow the cremation unless you are satisfied that the fact and cause of death have been definitely ascertained, or if not so ascertained that the Coroner has investigated the death and no longer requires the body for further examination;
- Power to request a pathologist to carry out a post-mortem examination if the cause of death has not been definitely ascertained or, in particular, the cause of death given on either Form Cremation 4 or Cremation 5 suggests that it might be due to poison, violence, an illegal operation, privation or neglect (in practice, these cases would normally be referred to the Coroner), subject to the consent of the appropriate person (as set out in Part 1 of the Human Tissue Act 2004) being obtained;
- Not to allow the cremation if such a post-mortem examination fails to reveal the cause of death, unless an inquest has been opened and a coroner has issued Form Cremation 6;
- Not to allow the cremation if there are other suspicious circumstances connected to the death of the deceased, whether revealed in the medical certificates or otherwise, unless an inquest has been opened and a coroner has given form Cremation 6;

- Not to allow the cremation until an inquest has been opened, if a coroner has given notice of his intention to open an inquest;

- To make such reports to the Secretary of State as may from time to time be required;

- To consider any representations from the applicant for cremation following his or her inspection of the medical certificates, and to refer the case to a coroner as necessary.

You should avoid any unnecessary delay to cremations but it is essential that you ensure that no cremation takes place unless all the relevant forms have been properly completed in accordance with the Regulations. You have the statutory power to reject inadequately completed forms, and you may refuse to authorise cremation until the forms have been completed satisfactorily. However, you must give your reasons if you refuse to authorise a cremation, and you should be aware that your decisions can be reviewed by the courts.

Cremation forms – general

All the cremation forms can be downloaded from our website at www.justice.gov.uk/cremation. Non-statutory versions of these forms should not be used. Crematoria must not change in any way the wording of the form, and you should not authorise any cremation which uses such a form.

Those who can sign Forms Cremation 4 and Cremation 5

Regulation 17 of the Cremation Regulations requires the confirmatory medical certificate (Form Cremation 5) to be completed by a registered medical practitioner of at least 5 years' standing. This means a registered medical practitioner who has been fully registered under the Medical Act 1983 for at least 5 years and, if paragraph 10 of Schedule 1 to the Medical Act 1983 (Amendment) Order 2002 has come into force, who has held a licence to practice for at least 5 years or since that paragraph came into force. All doctors signing these forms must be registered with the General Medical Council. In cases of doubt advice from the GMC's Contact Centre should be sought (Tel: 0161 923 6602).

Overseas doctors

Overseas doctors who are fully registered in the UK may sign Form Cremation 4 or, if fully registered in the UK for 5 years or more, may sign Form Cremation 5. Otherwise, it will depend on whether the doctor comes from and qualified outside the European Economic Area (EEA) or within it.

EC Directive 2005/36/EC (recognition of medical qualifications) have replaced earlier directives. Unlike previous Directives, the current Directive extends the principle of mutual recognition of professional qualifications to those awarded outside the EEA if the holder of a 'third country' qualification is an exempt person (i.e. a national of a relevant European State or entitled to be treated as such) and has three years' professional experience in the profession concerned on the territory of the relevant European State that initially recognised the qualification. (a list of the EEA member states and the places where primary European qualifications are obtained is at Annex A). Details of qualifications gained outside the EEA will need to be checked with the GMC.

A national of any EEA member state holding a primary European qualification is entitled to be registered in the UK as a fully registered medical practitioner. Experience acquired under the primary European qualification outside the UK should count towards any period of registration. Accordingly, an overseas doctor who has a primary European qualification in an EEA member state may sign a Form Cremation 5, provided he or she has held the qualification for five years and is registered in the UK. It may occasionally be necessary to ascertain the date and place of the qualification with the doctor concerned. If you have any doubt, you should check with the General Medical Council. Details of a doctor's qualification are published in the List of Registered Medical Practitioners which can be accessed through the GMC website.

[Information about EEA medical schools can be found at http://www.iime.org/database/europe.]

Corroboration of cause of death

Regulation 17 also requires that the registered medical practitioner who completes the confirmatory medical certificate (Form Cremation 5) must not be a relative of the deceased, or a relative, colleague or partner in the same practice or clinical team of the doctor who has completed the cremation certificate in Form Cremation 4. The same medical practitioner may not issue both Forms Cremation 4 and Cremation 5. Nor should the medical referee sign Form Cremation 5 except in an emergency.

The purpose of requiring two independent doctors to complete separate Forms Cremation 4 and Cremation 5 is to provide corroboration of the medical circumstances in which death took place. Accordingly, the doctors must be truly independent of one another. You must be satisfied that the doctors who complete Forms Cremation 4 and Cremation 5 are sufficiently independent of each other in all cases. The fact that it may sometimes be difficult to find an independent doctor is never a sufficient reason for failing to do so. Furthermore, outside the hospital setting, and particularly within the care-home setting, the patient's GP should not sign Form Cremation 5.

Similarly, where a junior hospital doctor has completed the certificate in Form Cremation 4, the doctor who completes the Form Cremation 5 should not have been in charge of the case, nor directly involved in the patient's treatment. Criminal and General Medical Council proceedings have been successfully brought against doctors who have falsely completed the forms.

Dentists

Dentists are not qualified to complete cremation certificates.

Completion of Forms Cremation 1, Cremation 4 and Cremation 5

General

It is essential that:

- All forms are completed in full
- All questions are answered
- No questions are deleted
- The forms are written in legible handwriting
- Any discrepancies between the forms as to the date and time of death are resolved.

Discrepancies as to date and time of death give particular cause for concern and you should always challenge them. It may, for example, be explained that the doctor saw the deceased, and only verified death, many hours after the family believe death occurred. This explanation should not be accepted without confirmation from all parties

Abbreviations for causes of death are unacceptable where they are unclear, unusual or ambiguous; in such cases, you should make further enquiries of the doctor concerned. There must be a hand-written signature, not an abbreviation or a stamp. It is for the doctor concerned to complete the certificate and not for another person to do so on his or her behalf. The doctor completing the confirmatory certificate should not seek to amend the certificate of the attending doctor, but should instead record any differences (e.g. as to the cause of death) on his or her own certificate, with an explanation of any differences.

It is for you to decide whether the information provided on the certificate allows you to authorise the cremation, with or without further enquiry. If there has been insufficient enquiry or there is an unclear cause of death, you are likely to need to make further enquiries of one or both doctors and in some cases the applicant.

Form Cremation 1: Application for cremation: the right of inspection (replacing form A)

There is no need for a counter-signature.

The application should be made by an executor or a near relative of the deceased. Where it is not, enquiries should be made to ascertain either that efforts to identify any executor or near relative have failed, or that the executor or near relative do not oppose the application, or wish to make the application themselves. In some cases, the next of kin will be described as being too upset to make the application personally and will have delegated this responsibility to another member of the family. This is understandable, but you may still need to make further enquiries to establish the true position.

The main additional question on Form Cremation 1 relates to the new right of inspection of forms Cremation 4 and Cremation 5. This is an important Shipman-related reform: the families of Shipman's victims believed that if they had had seen the cremation forms he had completed about their relative they would have recognised that the information was wrong, and he would have been exposed much sooner. You will not necessarily be involved in the process, but you may sometimes be asked to explain to applicants the answers on the Form. You may also need to take account of any concerns the applicant may have about the accuracy of the information on the forms, in case you have to refer the case to a coroner or for other investigation. The main purpose of the applicant’s right of inspection is to identify areas of concern which might require further investigation. The applicant’s right to inspect the forms should not depend upon whether he or she is willing to pay a fee to the referee for a medical explanation of the cause of death.

Form Cremation 2: Application for disposal of body parts (replacing form AA)

Broadly similar considerations apply to Form Cremation 2 as to Form Cremation 1 (see paragraphs 18 to 20 above). There is no right of inspection of any of the forms relating to body parts.

Form Cremation 3: Application for cremation of remains of stillborn baby

The 1930 Regulations had no statutory application forms in respect of a stillborn baby and we are aware that cremations took place solely on the basis of a registration document. The cremation of a stillborn baby will now require an application form, as well as either a form completed by a medical practitioner or midwife (see paragraph 46 below) or a declaration given by a person who can give information about the birth. It is expected that either one of the parents will complete this form, or a hospital bereavement officer will do so.

As there is no cause of death to investigate, the applicant has no right to inspect the medical form (Form Cremation 9). You need to be satisfied, as with Form Cremation 1, that the applicant is entitled to make the application and also that there is nothing contained within the information on the forms provided to suggest that the infant was not live-born.

Form Cremation 4: Medical certificate (replacing form B)

QUESTION 5: “USUAL MEDICAL PRACTITIONER”

With a few exceptions, the usual medical practitioner is taken to be the deceased’s general practitioner. Where the deceased has been an in-patient in hospital for a short period of time, in our view under 24 hours, the patient’s GP, rather than the hospital doctor who attended him or her for a majority of this period, should be regarded as the usual medical practitioner.

QUESTION 6: “PLEASE STATE FOR HOW LONG YOU ATTENDED THE DECEASED DURING THEIR LAST ILLNESS?”

The certifying doctor should have attended the deceased during his or her last illness. In the primary care setting, the deceased should have been treated by the certifying doctor during the days before the death. A general practitioner colleague may certify if he or she had seen the deceased outside the normally acceptable period (14 days) and the attending partner is unavailable although it is likely that such cases will have been discussed with a coroner. It should never be acceptable for the certifying doctor to have seen the body only after death and not treated the deceased during the last illness.

The minimum period of hospital care sufficient to meet the attendance requirement is normally 24 hours before death, unless it is a readmission, or a coroner has been informed. You may need to make enquiries to ascertain that the coroner's position has been established.

QUESTION 7: "PLEASE STATE THE NUMBER OF DAYS AND HOURS BEFORE THE DECEASED'S DEATH THAT YOU LAST SAW THEM ALIVE?"

The normal expectation is that the deceased will have been seen within 14 days before death; otherwise you should be satisfied that a coroner is aware of the case and is satisfied that no further investigation is necessary. You may accept a more extended period in a hospice or palliative care setting, if named nurses are available for consultation.

QUESTION 8: "PLEASE STATE THE DATE AND TIME THAT YOU SAW THE BODY OF THE DECEASED AND THE EXAMINATION YOU MADE OF THE BODY

Where there has been a non-coronial consented (or hospital) post-mortem examination carried out by the certifying medical attendant this should be indicated here and the cause of death in Question 10 will then be the findings of the examination. If there has been such a post-mortem examination performed by a registered medical practitioner of at least 5 years' standing (or, if not, was supervised by such a medical practitioner) the confirmatory medical certificate (Form Cremation 5) need not be completed.

QUESTION 9: DESCRIPTION OF SYMPTOMS AND OTHER CONDITIONS

This is a new section in free-text form, which gives the doctor an opportunity to explain how he or she arrived at the cause of death. The doctor should always refer to his or her medical notes, as well as his or her own observations as to the condition of the deceased. You should make further enquiries of the treating doctor if satisfactory explanations are not provided in this section.

QUESTION 11: CAUSE OF DEATH

You must ensure that all sections of this question have been answered. A mode of death on its own is never acceptable. The failure of an organ needs to explain the cause of that failure.

QUESTION 12 AND 13: OPERATIONS

The answers to these questions are intended both to identify possible surgical mishaps (although such deaths should have been referred to a coroner to investigate), and to indicate diagnostic procedures which contributed to the cause of death. If surgical procedures of potential significance are not included, this may call into question the reliability of the certificate.

QUESTIONS 14, 15 AND 16: THOSE NURSING THE DECEASED OR PRESENT AT THE DEATH

These questions are intended to help in gathering confirmatory information. Specific names (and contact details) should be given, as they will assist both the confirmatory doctor and you. Indeed, an unnamed nurse or family member with no contact details is unlikely to be of any value.

QUESTIONS 17, 18 AND 19: BACKGROUND AND CIRCUMSTANCES

These questions are likely to be answered in the negative, but if not they will invariably prompt further investigation and, in many cases, reference to a coroner.

QUESTIONS 20 AND 21 – REFERRAL TO A CORONER/CORONER'S OFFICE

If you are wholly satisfied as to the cause of death, you do not need to pursue any coronial investigation further. However, in cases of doubt you may wish to discuss the case further with a coroner or his or her staff. It is for you to be quite satisfied as to the cause of death before authorising cremation.

QUESTION 22 – REGISTRATION OF DEATH

In the majority of cases where the doctor registering the death has also completed Form Cremation 4, you are unlikely to need to make further enquiries about the registration. However, if the answer is "no", the confirmatory doctor (or you) should enquire of the doctor who has signed the medical certificate of the cause of death, in order to ensure that any possible discrepancies or uncertainties are resolved.

QUESTION 23 – REMOVAL OF IMPLANTS

Some implants may cause damage to the cremator, and may even be a serious health and safety risk if they explode. Fixion nail implants, inserted under pressure into bones, are of particular concern on health and safety grounds. You must be satisfied that any implant remaining within the body of the deceased is safe – otherwise it must be removed. Plastic hip joints, for example, are understood to cause no problem.

PART 3 – STATEMENT OF TRUTH

In cases of doubt (particularly where the form has been poorly completed), you should check the registered qualifications and the General Medical Council reference number on the General Medical Council's web-site. All signatories must be registered medical practitioners, although the date of registration is immaterial.

Form Cremation 5: Confirmatory Medical Certificate (replacing form C)

Form Cremation 5 must be completed, unless the categories in Regulations 16(c)(iii), 17(3), 18 or 24(2) apply, i.e. when a coroner has issued Form Cremation 6, there has been an anatomical examination of the body or there has been a consented post-mortem examination as described above (see paragraph 28). If Form Cremation 5 has been completed where there was no need for it, you should draw this to the attention of the doctor concerned, so that any fee paid may be refunded. You should also ask the funeral director to ensure that the applicant is not charged a fee for this unnecessary service.

The cause of death on Form Cremation 5 does not need to be the same as the one given on Form Cremation 4, but you should make enquiries about any discrepancy.

There should also be an affirmative answer to at least one of questions 2 to 5. This should not introduce significant delay to the completion of Form Cremation 5 or to the funeral arrangements. Nevertheless, Question 2 should be answered in the affirmative only if the signatory of Form Cremation 5 has questioned a medical practitioner other than the signatory of Form Cremation 4. It should be clear in response to each question whether the Form Cremation 5 doctor has spoken face-to-face to the other person or on the telephone.

Form Cremation 6: Certificate of Coroner (replacing form E)

A coroner must be notified if any suspicious circumstances come to your attention. Where a coroner has been consulted by the signatories of either Form Cremation 4 or Form Cremation 5, or by you, and the coroner considers that his/her involvement is unnecessary, the medical practitioner concerned or you, as appropriate, should record this next to Question 21 of Form Cremation 4, or after Question 7 of Form Cremation 5, or on a blank space on Form Cremation 8.

Coroners and medical referees sometimes take a different view about what is an acceptable or appropriate cause of death. You are not bound to accept the view of the coroner and may refuse to authorise cremation if you do not consider that you can. In such cases, you should advise the coroner of your decision and consider whether a post- mortem examination is necessary (see paragraphs 49 and 50).

Form Cremation 7: Anatomical Examination (replacing form H)

The relatives or executors of the deceased may apply for the cremation of a body which has been subject to anatomical examination in accordance with the Human Tissue Act 2004 or the previous Anatomy Acts, using Form Cremation 1 accompanied by Form Cremation.7. Alternatively, the authorities of the School of Anatomy or other such licensed institution may make the application. In these cases, you should be satisfied that the appropriate person has signed the application and that there is a satisfactory reason why the executor or near relative has not made the application. Where there is any doubt, you should make enquiries to ascertain whether efforts to identify any executor or near relative have failed, or whether the executor or near relative do not oppose the application, but do not wish to make the application themselves.

Application may occasionally be made for the cremation of parts remaining from a body donated under the provisions of the Human Tissue Act 2004 (or the legislation which that Act superseded) and which has already been separately cremated. Provided the retained body parts were removed in the course of the examination of the donated body, we take the view that it is reasonable to cremate on the authority of the existing Form Cremation 7.

Form Cremation 8: Certificate releasing body parts for cremation (replacing form DD)

Regulation 19 deals with the cremation of body parts removed following a post-mortem examination. Body parts may also be incinerated as desired and the medical referee will have no involvement in such cases. You will need to examine this form, together with the application form (Form Cremation 2) and to be satisfied that registration of the deceased has taken place [or a coroner has issued Form Cremation 6 in relation to this death].

Form Cremation 9: Certificate of stillbirth

You should be satisfied that the information on this form matches that on the application form for stillbirth (Form Cremation 3). Form Cremation 9 may be completed by either a registered medical practitioner or a registered midwife. In cases of doubt, you may wish to check registration with the appropriate governing body, either the General Medical Council or the Nursing and Midwifery Council.

Forms Cremation 10 (replacing form F), Cremation 12 (replacing form FF) and Cremation13: Medical referee's authority to cremate

When completing these forms, you should check the details of the name, address and occupation of the deceased against those on the other forms and registration document, if any, and query any discrepancies before you authorise cremation. The occupation of the deceased, combined with the apparent cause of death, may indicate that the person had died from an industrial disease. If you are concerned that this has been overlooked it may be helpful to discuss the matter with a coroner, as any failure accurately to record this information may have an impact on any outstanding industrial disease compensation claims. You should have some local knowledge of the industrial processes which take place, or have taken place, in your area. The Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1995 (1995 No 3163) lists industrial diseases which have to be reported. An electronic copy of these regulations is at www.opsi.gov.uk/SI/si1995/Uksi_19953163_en_1.htm.

You must always complete Part 2 of Form Cremation 10, 12 or 13.

Form Cremation 11: Certificate after Post-Mortem Examination (replacing form D)

On very rare occasions, the information on the forms (usually Cremation 4 and Cremation 5 if completed) may remain unsatisfactory and a coroner may be unwilling either to open an inquest or order a post-mortem examination. You may then refuse to authorise the cremation, giving your reasons. However, the family may still wish to have the body cremated. The only available option would then be for you to arrange for a post-mortem examination performed by a pathologist of your own or the cremation authority's choice, under Regulation 24(2). Any post-mortem must be carried out under the authority of a licence issued under the Human Tissue Act 2004.

In all cases of this kind, the consent of the family must be obtained as set out in the Human Tissue Act 2004. Although the Act provides for the deceased to have given consent for a post-mortem examination whilst still alive, this is likely to be uncommon. It will otherwise be necessary for the pathologist to be satisfied that an appropriate adult has a "qualifying relationship" with the deceased person, which is defined by section 54 of the 2004 Act as meaning a spouse, civil partner, parent, child, brother, sister, grandparent, grandchild, child of a brother or sister, stepfather, stepmother, half-brother, half-sister and friend of long standing. Any decision about any fee for the post-mortem examination will need to be agreed between the appropriate adult and other family members and the cremation authority. Subject to the number of tests required the fee may be quite substantial

Other matters

Causes of death – old age

The General Register Office advises that in certain circumstances, and if the deceased is over 80 years of age, ”old age” may be an acceptable cause of death on medical certificates. “Old age” alone, however, is unlikely to be an acceptable cause for cremation purposes, as you must be satisfied that the cause of death has been definitely ascertained. ”Old age” is commonly given as a cause of death where the deceased has been suffering from a number of conditions leading to death, but where it has not been possible to decide which particular condition led to the death. We cannot offer substantive guidance on a matter which is ultimately a clinical decision by the certifying doctor or doctors. However, you should be satisfied that that “old age” is an appropriate cause of death in all the circumstances. It cannot be used where the cause of death is properly “unascertained” and which should on that account be referred to a coroner.

Deaths Abroad

Where someone dies abroad and the body is repatriated to England or Wales for cremation, special arrangements apply, as set out under Regulation 14 of the Regulations.

Where someone dies in Scotland, you may accept the equivalent of the cremation application forms and those forms issued under the regulations applicable in Scotland. At present, these forms are those made under the Cremation (Scotland) Regulations 1935, as amended.

Where someone dies outside England, Wales or Scotland (but not Northern Ireland, the Isle of Man or the Channel Islands – see paragraph 55 below), you may accept an application form containing the particulars requested in Form Cremation 1, if this is accompanied by a declaration by the applicant that all particulars are true to the best of his or her knowledge and belief.

Where someone dies in Northern Ireland, the Isle of Man or the Channel Islands, you may accept certificates if they are substantially similar to Forms Cremation 4, 5, 6 and 7 and given in accordance with the law relating to cremation in force in Northern Ireland (i.e. the Cremation (Belfast) Regulations (Northern Ireland) 1961); the Isle of Man (Cremation Regulations 2000), the Bailiwick of Jersey or the Bailiwick of Guernsey, as the case may be.

In practice, most applications for cremation in relation to deaths outside the United Kingdom will require a Form Cremation 6 from a coroner, who will examine the relevant foreign documents including the death certificate. The coroner will need to be satisfied that the cause of death has been ascertained or it will be necessary to hold an inquest. You are not expected to investigate deaths of this kind.

Stillbirths outside England and Wales

In the case of stillbirths outside England and Wales, you may accept under Regulation 14(4) a medical certificate of stillbirth given by a registered medical practitioner or registered midwife (or a person entitled to practice as a medical practitioner or midwife) in the place where the stillbirth occurred. You would do this after making such enquiries as you consider necessary, provided you are satisfied that the baby was stillborn and that there is no reason for further examination. In the case of stillbirths in Scotland, if cremation is authorised on presentation of a certificate of registration under the hand to the Registrar of Births, Deaths and Marriages in the form of Schedule 8 appended to the Registration of Births, Still-births, Deaths and Marriages (Prescription of Forms) (Scotland) Regulations 1965, the General Register Office for Scotland should be notified (at New Register House, Edinburgh EH1 3YT) to ensure that the stillbirth is registered in Scotland.

Unidentified Remains

You should not consider applications for the cremation of unidentified remains unless a coroner's Form Cremation 6 has been produced. The circumstances which make it impossible to identify the remains will also require the death to be reported to a coroner and adequate enquiry will then have taken place.

Cremation of non-viable foetal remains

Foetal remains under 24 weeks gestation are not subject to the provisions of the Cremation Act or Regulations, although most crematoria will be prepared to cremate such remains at their discretion. You should not complete a Form Cremation 9 to authorise their cremation. If you are asked by crematoria managers and staff for professional advice on an application to cremate pre-viable foetuses, it is entirely a matter for you whether you provide such advice.

Annex A – European Economic Area

European Union Members: Universities where Primary European Qualifications can be obtained within each state

- Austria – Graz, Innsbruck, Salzburg, Salzburg (Paracelsus), Vienna (Wien)

Work Smart Session - MRCP Part 1

Time taken:

Question: 1 of 3

A 36-year-old alcoholic has an endoscopy some 16 hours after his admission with a variceal haemorrhage. This is his second admission in 6 months with an upper GI bleed and he has required a 4 unit blood transfusion. Endoscopy reveals a number of large varices, including one with adherent clot.

Which of the following is the therapy with the best evidence with respect to reducing the risk of a variceal bleed over the next few months?

(Please select 1 option)

○	**A** High dose omeprazole
○	**B** Propanolol
○	**C** Sclerotherapy
○	**D** Variceal banding
○	**E** Vasopressin

A 36-year-old alcoholic has an endoscopy some 16 hours after his admission with a variceal haemorrhage. This is his second admission in 6 months with an upper GI bleed and he has required a 4 unit blood transfusion. Endoscopy reveals a number of large varices, including one with adherent clot.

Which of the following is the therapy with the best evidence with respect to reducing the risk of a variceal bleed over the next few months?

(Please select 1 option)

○	**A** High dose omeprazole
○	**B** Propanolol
○	**C** Sclerotherapy
◉	**D** Variceal banding ✓ Correct
○	**E** Vasopressin

The answer is D), variceal banding. Banding is proven to eliminate varices with fewer procedures and complications than injection sclerotherapy. A recent trial has demonstrated that beta blockade and sclerotherapy is better than beta blockade alone in prophylaxis against bleeding. The vasopressin analogue, terlipressin is used to control bleeding acutely, along with somatostatin analogues.

Work Smart Session - MRCP Part 1

Time taken: 2 mins 32 secs

Question: 2 of 3

A 34-year-old skier comes to the Emergency Department with pain and swelling over the first metacarpophalangeal joint (MCP joint) after a fall whilst practicing on the dry ski slope. On examination there is extensive swelling and bruising over the ulnar aspect of the joint.

What is he most likely to have injured?

(Please select 1 option)

- **A** Accessory collateral ligament
- **B** Proximal phalanx
- **C** Radial collateral ligament
- **D** Scaphoid bone
- **E** Ulnar collateral ligament

Question: 2 of 3

A 34-year-old skier comes to the Emergency Department with pain and swelling over the first metacarpophalangeal joint (MCP joint) after a fall whilst practicing on the dry ski slope. On examination there is extensive swelling and bruising over the ulnar aspect of the joint.

What is he most likely to have injured?

(Please select 1 option)

○	**A** Accessory collateral ligament
◉	**B** Proximal phalanx ✕ Incorrect answer selected
○	**C** Radial collateral ligament
○	**D** Scaphoid bone
○	**E** Ulnar collateral ligament ← This is the correct answer

The answer is E), ulnar collateral ligament. Skier's thumb was formerly known as gamekeeper's thumb, and it relates to injury to the base of the thumb, resulting in damage/ rupture of the ulnar collateral ligament. Once acute swelling has subsided, then gross instability of the thumb may result. Where a complete tear of the ligament is suspected, MRI may be valuable in confirming the diagnosis, as surgical repair is required. In cases of a partial rupture, immobilisation in a thumb spica is the standard therapy.

A 24-year-old woman who is known to suffer from mitral valve prolapse comes to the emergency department complaining of sudden, terrible, tearing pain between her shoulder blades. She notes that her mother died suddenly when she was aged 38.

On examination her BP is 166/94 mmHg, her pulse is 95 and regular. Her chest is clear. Her skin seems rather thin and pale white, you can see extensive bruising over her shins, and her blood vessels are easily visible as you look at her arms.

She has a number of keloid scars, which appear to have occurred after relatively minor skin injuries. She is given oxygen and diamorphine for pain relief.

Investigations show

Haemoglobin	12.0 g/dl	(11.5-16.5)
White cells	6.8 x 10^9/L	(4-11)
Platelets	180 x 10^9/L	(150-400)
Sodium	140 mmol/l	(135-146)
Potassium	4.2 mmol/l	(3.5-5)
Creatinine	90 µmol/l	(79-118)
AP chest x ray	Mediastinum width 9.5 cm	
ECG	3 mm inferior ST elevation	

Which of the following is the most appropriate initial therapy?

(Please select 1 option)

- ○ Alteplase

Haemoglobin	12.0 g/dl	(11.5-16.5)
White cells	6.8 x 10^9/L	(4-11)
Platelets	180 x 10^9/L	(150-400)
Sodium	140 mmol/l	(135-146)
Potassium	4.2 mmol/l	(3.5-5)
Creatinine	90 µmol/l	(79-118)
AP chest x ray	Mediastinum width 9.5 cm	
ECG	3 mm inferior ST elevation	

Which of the following is the most appropriate initial therapy?

(Please select 1 option)

- Alteplase
- Angioplasty
- Heparin and IV nitrate
- IV beta-blockade
- Streptokinase

Submit answer | Skip question | Tag Question | Remove question

AP chest x ray	Mediastinum width 9.5 cm
ECG	3 mm inferior ST elevation

Which of the following is the most appropriate initial therapy?

(Please select 1 option)

○	Alteplase
○	Angioplasty
○	Heparin and IV nitrate
◉	IV beta-blockade ✓ Correct
○	Streptokinase

The history is highly suspicious of aortic dissection, with involvement of the right coronary artery suggesting a type A dissection.

This patient needs beta-blockade to reduce her BP and myocardial oxygen demand and investigation to confirm the diagnosis. Most emergency departments have rapid access to CT pulmonary angiogram and this is the investigation of choice.

Regarding type A dissection, progression to surgery is inevitable.

The underlying clinical features are suggestive of Ehlers-Danlos syndrome which puts her at high risk of vascular rupture/dissections.

Work Smart Session - MRCP Part 1

Time taken:

Question: 1 of 100

A patient who was recently admitted to the medical receiving unit with general malaise has been found to have deranged renal function. Your registrar asks you to arrange "an urgent scan" to exclude obstruction of the kidneys.

Which of the following is most appropriate?

(Please select 1 option)

- Ultrasound renal tract
- CT KUB (Kidneys, Ureters and Bladder)
- MRI kidneys
- MR angiography of renal tract
- Plain abdominal x ray

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Question: 10 of 100

A 59-year-old man with chronic renal failure comes to the surgery complaining of tiredness and lethargy. He has a longstanding history of type 1 diabetes and takes a range of medications.

On examination his BP is 145/84 mmHg.

Investigations show

Haemoglobin	9.4 g/dl	(13.5-18)
White cell count	6.4 x 10^9/l	(4-10)
Platelets	162 x 10^9/l	(150-400)
Sodium	140 mmol/l	(134-143)
Potassium	5.0 mmol/l	(3.5-5)
Creatinine	219 µmol/l	(60-120)
Ferritin	10 Microgram/l	(20-60)
Faecal occult blood	Negative	
Urine	Protein ++	

Which of the following is the most appropriate next step?

(Please select 1 option)

- ○ Erythropoietin
- ○ IV iron transfusion
- ○ Oral ferrous sulphate
- ○ Referral for lower GI endoscopy
- ○ Referral for upper GI endoscopy

Work Smart Session - MRCP Part 1

Question: 100 of 100

A 65-year-old male patient is admitted with renal failure and is diagnosed with acute tubular necrosis (ATN).

Which of the following is least likely to be the cause of acute tubular necrosis?

(Please select 1 option)

- Corticosteroid therapy
- Hypertension
- Hypovolaemia
- Paracetamol poisoning
- Rhabdomyolysis

Submit answer | Skip question | Tag Question | Remove question

A 65-year-old male patient is admitted with renal failure and is diagnosed with acute tubular necrosis (ATN).

Which of the following is least likely to be the cause of acute tubular necrosis?

(Please select 1 option)

◉	Corticosteroid therapy ✓ Correct
○	Hypertension
○	Hypovolaemia
○	Paracetamol poisoning
○	Rhabdomyolysis

Renal failure from ATN occurs in 25% patients with severe hepatic damage.

Accelerated hypertension can cause small vessel obstruction with proliferative endarteritis of intralobular arteries and fibrinoid necrosis of afferent arterioles and glomerular capillary tuft.

Corticosteroid therapy has not been associated with ATN.

Other causes of ATN include

- Hypotension
- Hepatic failure
- Eclampsia and
- Drugs such as aminoglycosides, cephalosporins, cisplatin, amphotericin.

Sodium	140 mmol/l	(134-143)
Potassium	5.0 mmol/l	(3.5-5)
Creatinine	219 µmol/l	(60-120)
Ferritin	10 Microgram/l	(20-60)
Faecal occult blood	Negative	
Urine	Protein ++	

Which of the following is the most appropriate next step?

(Please select 1 option)

- ○ Erythropoietin
- ○ IV iron transfusion ← This is the correct answer
- ○ Oral ferrous sulphate
- ◉ Referral for lower GI endoscopy ✕ Incorrect answer selected
- ○ Referral for upper GI endoscopy

This patient has a low serum ferritin, a common occurrence in patients with chronic renal failure. Often patients with chronic renal failure struggle with their eating, and have deficient iron absorption. As such IV iron transfusion is the therapy of choice.

Once iron stores are restored and ferritin is in the normal range, if the patient is still anaemic then erythropoietin would be the next appropriate option.

Given the FOB is negative, GI blood loss is less likely as a cause of his anaemia.

Time taken: 1 hrs 39 mins 14 secs

Work Smart Session - MRCP Part 1

Question: 11 of 100

A 63-year-old man, with chronic renal failure and type 2 diabetes, presents to the surgery complaining of generalised aching. He takes twice daily mixed insulin for his diabetes, and ramipril for vascular risk modification.

On examination his BP is 155/92 mmHg, pulse is 75 and regular. Physical examination is otherwise unremarkable.

Haemoglobin	10.9 g/dl	(13.5-18)
White cell count	6.1 x 10^9/l	(4-10)
Platelets	191 x 10^9/l	(150-400)
Sodium	140 mmol/l	(134-143)
Potassium	5.3 mmol/l	(3.5-5)
Creatinine	320 µmol/l	(60-120)
Calcium	2.05 Mmol/l	(2.2-2.67)
Urine	Protein +	

Which of the following is the most likely underlying diagnosis?

(Please select 1 option)

- Hypoparathyroidism
- Primary hyperparathyroidism
- Secondary hyperparathyroidism
- Tertiary hyperparathyroidism
- Vitamin D intoxication

Calcium	2.05 Mmol/l	(2.2-2.67)
Urine	Protein +	

Which of the following is the most likely underlying diagnosis?

(Please select 1 option)

- ○ Hypoparathyroidism
- ○ Primary hyperparathyroidism
- ◉ Secondary hyperparathyroidism ✓ Correct
- ○ Tertiary hyperparathyroidism
- ○ Vitamin D intoxication

Chronic renal failure leads to low levels of hydroxylated vitamin D, and hence to hypocalcaemia. This leads to a secondary increase in parathyroid hormone levels.

The second, fourth and fifth options will cause hypercalcaemia.

Standard therapy of choice is three times per week 1-alpha calcidol. Once the calcium approaches the normal range there is often an associated fall in parathyroid levels.

Cinacalcet may be used in patients with end-stage renal disease receiving maintenance haemodialysis, with frequent monitoring of parathormone and calcium.

Time taken: 1 hrs 43 mins 2 secs

Work Smart Session - MRCP Part 1

Question: 12 of 100

In which of the following patients is an ACE inhibitor contraindicated?

(Please select 1 option)

○	A 24-year-old woman with type 1 diabetes and microalbuminuria, who wants to start a family
○	A 28-year-old woman with reflux nephropathy and hypertension
○	A 34-year-old man with essential hypertension and a BMI of 32
◉	A 34-year-old woman with hypertension and a horseshoe kidney
○	A 62-year-old type 2 diabetes patient who has microalbuminuria and a stable creatinine of 210

Submit answer | Skip question | Tag Question | Remove question

- Help

○	A 24-year-old woman with type 1 diabetes and microalbuminuria, who wants to start a family ← This is the correct answer
◉	A 28-year-old woman with reflux nephropathy and hypertension ✕ Incorrect answer selected
○	A 34-year-old man with essential hypertension and a BMI of 32
○	A 34-year-old woman with hypertension and a horseshoe kidney
○	A 62-year-old type 2 diabetes patient who has microalbuminuria and a stable creatinine of 210

ACE inhibitors are contraindicated in pregnancy. There is an increase in congenital cardiac and neurological abnormalities (New England Journal of Medicine 2006 354:2443-2451); and despite the fact this woman has microalbuminuria, use of an ACE inhibitor is not recommended.

In patients with elevated creatinine and microalbuminuria, use of an ACE inhibitor is still a reasonable option, as it has been proven to delay both further deterioration of creatinine and worsening albuminuria.

With respect to essential hypertension and a raised BMI, an ACE inhibitor may be appropriate; other options include a calcium antagonist.

Regarding beta-blockers and thiazides, evidence suggests they may increase insulin resistance and risk of diabetes, hence you may choose to avoid them here.

Other contraindications to ACE inhibition include

- Angio-oedema
- Breast feeding
- Significant renal artery stenosis.

Question: 13 of 100

A 51-year-old male comes to the surgery complaining of nausea and fatigue. You have previously seen him with symptoms of sinusitis, and a saddle nose deformity.

Most recently he has begun to complain of shortness of breath and a chronic cough.

On examination he is hypertensive at 160/92 mmHg. There are bilateral inspiratory crackles on auscultation of the chest.

Investigations show

Haemoglobin	11.8 g/dl	(13.5-18)
White cell count	10.1 x 10^9/l	(4-10)
Platelets	182 x 10^9/l	(150-400)
Sodium	141 mmol/l	(134-143)
Potassium	5.5 mmol/l	(3.5-5)
Creatinine	230 µmol/l	(60-120)
ESR	72	(<10)
Urine	Blood++ Protein ++	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- Goodpasture's syndrome
- IgA nephropathy
- Membranous nephropathy
- Minimal change disease
- Wegener's granulomatosis

Submit answer | Skip question | Tag Question | Remove question

Protein ++

Which of the following is the most likely diagnosis?

(Please select 1 option)

○	Goodpasture's syndrome
○	IgA nephropathy
○	Membranous nephropathy
○	Minimal change disease
◉	Wegener's granulomatosis ✓ Correct

Wegener's granulomatosis is a multi-system disorder characterised by necrotising granulomas of medium and small blood vessels. Patients have constitutional symptoms such as fever, lethargy and weight loss.

Organ specific involvement includes

- Eyes
- Upper airway
- Lung
- Renal
- Nervous system
- Skin
- Joints.

Men are affected slightly more often than women and typically present in the fourth or fifth decade. Patients often present with ocular or ENT symptoms for sometime before a diagnosis is made.

Autoimmune profile is likely to reveal a positive circulating anti-neutrophil cytoplasmic antibody (cANCA), and renal biopsy is the usual way to obtain a tissue diagnosis.

Treatment is with high dose steroids and cyclophosphamide, which has revolutionised this disease which is otherwise rapidly fatal.

Question: 14 of 100

A 7-year-old boy is brought to the surgery by his mother. He has become unwell with severe diarrhoea which is now mixed with blood.

History of note is a visit to a model farm a few days earlier. He is nauseous, has a severe headache, and feels very unwell.

On examination he is pyrexial 38.2°C, his BP is 142/88 mmHg. He has a soft, diffusely tender abdomen.

Investigations show

Haemoglobin	9.2 g/dl	(13.5-18)
White cell count	11.9 x 10^9/l	(4-10)
Platelets	76 x 10^9/l	(150-400)
Sodium	141 mmol/l	(134-143)
Potassium	4.9 mmol/l	(3.5-5)
Creatinine	192 µmol/l	(60-120)
Bilirubin	92 µmol/l	(<17)
Urine	Blood++ Protein ++	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- *Brucella* infection
- *Campylobacter* infection
- *Escherichia coli* infection
- *Salmonella* infection
- *Shigella* infection

Submit answer | Skip question | Tag Question | Remove question

Question: 15 of 100

A 12-year-old boy presents to the surgery with peri-orbital and mild ankle oedema which has increased over the past few weeks.

Other history of note is a recent upper respiratory tract infection. He has been feeling increasingly tired and lethargic over the past few weeks.

On examination his BP is 138/72 mmHg. He has periorbital oedema and pitting ankle oedema.

Investigations show

Haemoglobin	12.4 g/dl	(13.5-18)
White cell count	7.8 x 10^9/l	(4-10)
Platelets	191 x 10^9/l	(150-400)
Sodium	141 mmol/l	(134-143)
Potassium	4.6 mmol/l	(3.5-5)
Creatinine	104 µmol/l	(60-120)
Serum albumin	28 g/l	(35-50)
Urine	Protein ++	

Which of the following is the most likely cause?

(Please select 1 option)

- IgA nephropathy
- Alport's syndrome
- Membranous nephropathy
- Minimal change nephropathy
- Post streptococcal glomerulonephritis

Question: 15 of 100

A 12-year-old boy presents to the surgery with peri-orbital and mild ankle oedema which has increased over the past few weeks.

Other history of note is a recent upper respiratory tract infection. He has been feeling increasingly tired and lethargic over the past few weeks.

On examination his BP is 138/72 mmHg. He has periorbital oedema and pitting ankle oedema.

Investigations show

Haemoglobin	12.4 g/dl	(13.5-18)
White cell count	7.8 x 10^9/l	(4-10)
Platelets	191 x 10^9/l	(150-400)
Sodium	141 mmol/l	(134-143)
Potassium	4.6 mmol/l	(3.5-5)
Creatinine	104 µmol/l	(60-120)
Serum albumin	28 g/l	(35-50)
Urine	Protein ++	

Which of the following is the most likely cause?

(Please select 1 option)

- IgA nephropathy
- Alport's syndrome
- Membranous nephropathy
- Minimal change nephropathy
- Post streptococcal glomerulonephritis

Sodium	141 mmol/l	(134-143)
Potassium	4.6 mmol/l	(3.5-5)
Creatinine	104 µmol/l	(60-120)
Serum albumin	28 g/l	(35-50)
Urine	Protein ++	

Which of the following is the most likely cause?

(Please select 1 option)

- ◉ IgA nephropathy ✕ Incorrect answer selected
- ○ Alport's syndrome
- ○ Membranous nephropathy
- ○ Minimal change nephropathy ← This is the correct answer
- ○ Post streptococcal glomerulonephritis

The history of periorbital oedema, normal blood pressure and creatinine, but proteinuria and low albumin is typical of minimal change disease.

The condition is much more common in this age range than membranous nephropathy.

The important point about making the diagnosis is that the condition responds to corticosteroid therapy in 90% or more of sufferers in childhood within two weeks, although treatment is usually continued for a period of eight weeks.

Question: 16 of 100

A 28-year-old man is referred to you by the practice nurse for hypertension management. She has seen him three times over the past four months and his BP is persistently elevated at around 155/92 mmHg.

Your partner has seen him previously for some non-specific right upper quadrant abdominal pain.

On examination of the abdomen you can feel bilateral enlarged kidneys, and a liver edge.

Investigations show

Haemoglobin	12.5 g/dl	(13.5-18)
White cell count	6.4 x 10^9/l	(4-10)
Platelets	182 x 10^9/l	(150-400)
Sodium	139 mmol/l	(134-143)
Potassium	4.8 mmol/l	(3.5-5)
Creatinine	182 µmol/l	(60-120)
Glucose	4.5 Mmol/l	(<6.0)
Urine	Blood ++ Protein -	

Which one of the following is most closely associated with his underlying condition?

(Please select 1 option)

- Aortic stenosis
- Coarctation of the aorta
- Diabetes mellitus
- Mitral valve prolapse
- Tricuspid stenosis

Potassium	4.8 mmol/l	(3.5-5)
Creatinine	182 µmol/l	(60-120)
Glucose	4.5 Mmol/l	(<6.0)
Urine	Blood ++ Protein -	

Which one of the following is most closely associated with his underlying condition?

(Please select 1 option)

◉	Aortic stenosis ✕ Incorrect answer selected
○	Coarctation of the aorta
○	Diabetes mellitus
○	Mitral valve prolapse ← This is the correct answer
○	Tricuspid stenosis

A young man presenting with renal failure, haematuria and liver and renal masses raises the suspicion of polycystic kidney disease.

Associated liver cysts are found in around 80% of individuals with polycystic kidney disease. Pancreatic cysts are rarer, and may in some cases be associated with recurrent pancreatitis.

Patients are at increased risk of renal stones, but the predominant increase is seen in urate stones, rather than other types.

Up to 25% of patients may have some degree of mitral valve prolapse.

MODY 5 is associated with hepatic and renal cysts and diabetes mellitus, but that is less likely to be the diagnosis here in the presence of a normal glucose.

Polycystic kidney disease carries an autosomal dominant pattern of inheritance, but may occur as a de novo mutation in 5%.

Work Smart Session - MRCP Part 1

Question: 17 of 100

A 62-year-old man with a history of type 2 diabetes and renal failure comes to the emergency department. He currently uses continuous ambulatory peritoneal dialysis, and has noticed an increase in his insulin requirements over the past 24 hours, dull abdominal pain, and now has a cloudy bag.

On examination he is pyrexial 37.8°C and looks unwell, his blood pressure is 142/88 mmHg, with a pulse of 90. His abdomen is generally tender to palpation.

Haemoglobin	10.4 g/dl	(13.5-18)
White cell count	13.6 x 10^9/l	(4-10)
Platelets	190 x 10^9/l	(150-400)
Sodium	137 mmol/l	(134-143)
Potassium	5.3 mmol/l	(3.5-5)
Creatinine	342 µmol/l	(60-120)
CRP	88	(<10)
Peritoneal dialysis fluid	>100 white cells/cm^2	

Which of the following organisms is most likely to be responsible?

(Please select 1 option)

- *C. albicans*
- *S. aureus*
- *S. faecalis*
- *S. pyogenes*
- *S. viridians*

Submit answer | Skip question | Tag Question | Remove question

Questions Set : REF55101

Haemoglobin	10.4 g/dl	(13.5-18)
White cell count	13.6 x 10^9/l	(4-10)
Platelets	190 x 10^9/l	(150-400)
Sodium	137 mmol/l	(134-143)
Potassium	5.3 mmol/l	(3.5-5)
Creatinine	342 µmol/l	(60-120)
CRP	88	(<10)
Peritoneal dialysis fluid	>100 white cells/cm^2	

Which of the following organisms is most likely to be responsible?

(Please select 1 option)

○	*C. albicans*
◉	*S. aureus* ✓ Correct
○	*S. faecalis*
○	*S. pyogenes*
○	*S. viridians*

Staphylococcus aureus, *Staphylococcus epidermidis*, *Pseudomonas aeruginosa*, and *Escherichia coli* are the commonest causes of peritonitis in peritoneal dialysis patients. Severe infections may be polymicrobial.

Treatment with intraperitoneal antibiotics is superior to intravenous antibiotics. Persistent or recurrent peritonitis should prompt catheter removal.

EN 3:47 PM 3/1/2011

commenced him on amlodipine 5 mg daily.

You understand on further questioning that his brother has haematuria and renal impairment and his father died of a stroke at the age of 42. On examination his blood pressure is 152/88 mmHg, he has bilateral ballotable kidneys.

Investigations show

Haemoglobin	13.4 g/dl	(13.5-18)
White cell count	6.0 x 10^9/l	(4-10)
Platelets	242 x 10^9/l	(150-400)
Sodium	140 mmol/l	(134-143)
Potassium	4.7 mmol/l	(3.5-5)
Creatinine	162 µ/l	(60-120)
Urine	Blood ++ Protein -	

Which of the following is the investigation most appropriate to elucidate the underlying diagnosis?

(Please select 1 option)

○	Contrast CT abdomen
○	Cystoscopy
○	Intravenous pyelogram (IVP)
○	Plain abdominal film
◉	Ultrasound abdomen ✓ Correct

The fact that his father and brother are both affected is suggestive of an autosomal dominant inherited disorder, probably autosomal dominant polycystic kidney disease (ADPKD).

Given that his father had a stroke at a young age, this raises the possibility of a berry aneurysm and subsequent subarachnoid haemorrhage.

A 30-year-old Caucasian man with HIV infection was found to have high blood pressure at 180/118 mmHg (high on several occasions). His father died of stroke at the age of 51.

Routine blood test showed:

Sodium	145 mmol/l	(135-145)
Potassium	3.4 mmol/l	(3.5-5.1)
Creatinine	99 mmol/l	(60-110)
Urea	4.9 mmol/l	(2.9-9.0)
Urinanalysis	No proteinuria	
Plasma aldosterone	815 pmol/l	(28-445)
Plasma renin	0.3 ng/ml/h	(0.7-5)
Renal ultrasound	Normal-sized kidneys	
CD4	769 cells/ml	
HIV RNA	4531 copies/ml	

He was not on any antiretroviral therapy.

What is the most likely cause of his high arterial blood pressure?

(Please select 1 option)

- ○ Adult polycystic kidney
- ○ Conn's syndrome
- ○ Familial essential hypertension
- ○ HIV associated nephropathy
- ○ Non-Hodgkin's lymphoma involving kidneys

(Please select 1 option)

○	Adult polycystic kidney
◉	Conn's syndrome ✓ Correct
○	Familial essential hypertension
○	HIV associated nephropathy
○	Non-Hodgkin's lymphoma involving kidneys

High aldosterone and low renin levels indicate primary hyperaldosteronism which accounts for up to 10% of all hypertensive patients. It is the most prevalent form of secondary hypertension.

Potassium level is often normal or the lower limit of normal and so hypokalaemia is not a prerequisite for diagnosis of Conn's syndrome.

Normal renal ultrasound makes adult polycystic kidney an unlikely cause of high blood pressure.

High aldosterone and low renin level is not seen in familial essential hypertension.

HIV associated nephropathy causes proteinuria.

Non-Hodgkin's lymphoma is often associated with low CD4 count.

Which of the following is most appropriate?

(Please select 1 option)

◉	Ultrasound renal tract ✓ Correct
○	CT KUB (Kidneys, Ureters and Bladder)
○	MRI kidneys
○	MR angiography of renal tract
○	Plain abdominal x ray

Acute imaging of the kidneys is intended primarily to exclude obstructive uropathy, which would be demonstrated on ultrasound imaging. Ultrasound imaging is a safe, non-invasive means to rapidly exclude a correctable cause of renal impairment. It is readily available in most hospitals and can be performed by a sonographer or radiologist.

A CT KUB is indicated when the USS (and clinical history) is suggestive of the presence of renal calculi, whether or not they are causing obstruction.

MR imaging of the kidneys can help determining the nature of a lesion seen on ultrasound imaging. It is expensive, time-consuming, and not available in all locations. Furthermore many patients with magnetic materials inserted eg. Pacemakers, defibrilators are precluded from entering the strong magnetic field. These factors preclude its use as a first-line approach to excluding acute obstruction of the kidney.

MR angiography is helpful to exclude renal artery stenosis. This will not confirm or refute the presence of post-renal obstruction.

A plain abdominal x-ray will occasionally demonstrate the presence of a radio-opaque renal calculi, but cannot confirm or refute the presence of post-renal obstruction. It should not be done routinely in all patients with acute renal impairment unless there is a strong clinical suspicion of renal calculi (in which case most patients will proceed to having a CT KUB examination).

Work Smart Session - MRCP Part 1

Question: 2 of 100

A 63-year-old woman is admitted to hospital with a three day history of diarrhoea and vomiting. Her family tell you she has been virtually unable to eat or drink, but has managed to take her tablets during that time. Her past medical history includes essential hypertension and ischaemic heart disease. Her current medication consists aspirin 75 mg daily, ramipril 5 mg daily, simvastatin 40 mg daily. Her admission bloods demonstrate: sodium 144, potassium 4.1, urea 10.8, creatinine 195.

Which of the following is most appropriate?

(Please select 1 option)

○	Give clopidogrel 300 mg stat
○	Withhold ramipril
○	Double dose of ramipril
○	Give loperamide
○	Withhold aspirin

Work Smart Session - MRCP Part 1

Question: 20 of 100

A 17-year-old woman underwent a renal transplant. She was concerned about the effects of long-term ciclosporin treatment.

Which one of the following is a common adverse effect of this drug?

(Please select 1 option)

○	Alopecia
○	Bone marrow depression
○	Hepatotoxicity
◉	Nephrotoxicity ✓ Correct
○	Paraesthesia

Ciclosporin causes hypertrichosis rather than alopecia and the most frequent adverse side effect of this drug is nephrotoxicity.

Post renal transplant, the two most common causes of declining renal function are graft rejection and ciclosporin toxicity.

Hepatotoxicity and paraesthesia are less common side effects of the drug.

Work Smart Session - MRCP Part 1

Question: 21 of 100

A 16-year-old female presents with a three year history of recurrent colicky loin pain. One year ago she passed a renal calculus.

Twenty four hour urine collection showed normal levels of calcium, phosphate and urate, but elevated levels of arginine, cystine, lysine and ornithine.

Which one of the following features is characteristic of this condition?

(Please select 1 option)

○	Accumulation of cystine in collecting system
○	Autosomal dominant inheritance
◉	Cystine deposits within the cornea
○	Functional defects within the glomeruli
○	Radiolucent renal stone formation

Question: 21 of 100

A 16-year-old female presents with a three year history of recurrent colicky loin pain. One year ago she passed a renal calculus.

Twenty four hour urine collection showed normal levels of calcium, phosphate and urate, but elevated levels of arginine, cystine, lysine and ornithine.

Which one of the following features is characteristic of this condition?

(Please select 1 option)

○	Accumulation of cystine in collecting system ← This is the correct answer
○	Autosomal dominant inheritance
○	Cystine deposits within the cornea
○	Functional defects within the glomeruli
◉	Radiolucent renal stone formation ✕ Incorrect answer selected

This condition is typical of cystinuria/nephropathic cystinosis, an autosomal recessive genetic defect in membrane transport for cystine, lysine, ornithine and arginine in epithelial cells.

The disease is characterised by recurrent nephrolithiasis.

Radiolucent stones are not specific for this condition and may be seen with uric acid stones.

Work Smart Session - MRCP Part 1

Question: 22 of 100

A 65-year-old man presents with renal colic. The following day he passes a stone in his urine with analysis revealing that it is composed of uric acid.

Which one of the following is the most likely cause of this type of renal stone?

(Please select 1 option)

○	Allopurinol
○	Chronic renal failure
○	Primary hyperparathyroidism
○	Secondary polycythaemia
○	Thiazide diuretics

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Chronic renal failure
○	Primary hyperparathyroidism
◉	Secondary polycythaemia ✕ Incorrect answer selected
○	Thiazide diuretics ← This is the correct answer

Uric acid stones occur in 5-25% of all cases of nephrolithiasis. They are associated with hyperuricaemia and hyperuricosuria.

Predisposing factors for uric acid stone formation are

- Dehydration
- High purine load (high protein diet)
- As a primary factor in idiopathic gout
- Associated with high cell turnover (for example, haematological malignancy).

Chronic renal failure is incorrect, as there is hyperuricaemia without hyperuricosuria.

Hyperparathyroidism is associated with calcium stones, not uric acid stones.

Primary polycythaemia would predispose to uric acid stone formation, whereas secondary polycythaemia does not.

Allopurinol is prescribed to treat gout and prevents uric acid formation, hence it reduces the frequency of uric acid stones.

The correct answer is thiazide diuretics. Thiazide diuretics cause hyperuricaemia and can predispose to hyperuricosuria and uric acid stone formation. Uric acid stones are also associated with underlying hypertension.

Thiazide diuretics are used to treat calcium stones as they increase the reabsorption of calcium from the proximal tubules, preventing hypercalciuria.

Question: 23 of 100

A 52-year-old woman presents with left loin pain. Past history included hypertension and progressive cognitive decline.

On examination she was pyrexial, had livedo reticularis and a blood pressure of 180/100 mmHg. Examination of the abdomen revealed no masses but there was tenderness in the left flank.

Investigations revealed:

Haemoglobin	12.9 g/dl	(11.5-16.5)
White cell count	8.7 x 10^9/l	(4-11)
Platelet count	83 x 10^9/l	(150-400)
Serum creatinine	106 mol/l	(60-110)

Urine dipstick analysis:
Blood +++
Protein +

Which one of the following tests is most likely to be positive?

(Please select 1 option)

- Anti-cardiolipin antibody
- Anti-glomerular basement membrane antibody
- Anti-mitochondrial antibody
- Anti-neutrophil cytoplasmic antibody
- Anti-streptolysin O antibody

Submit answer | Skip question | Tag Question | Remove question

Serum creatinine	106 mol/l	(60-110)

Urine dipstick analysis:
Blood +++
Protein +

Which one of the following tests is most likely to be positive?

(Please select 1 option)

◉	Anti-cardiolipin antibody ✓ Correct
○	Anti-glomerular basement membrane antibody
○	Anti-mitochondrial antibody
○	Anti-neutrophil cytoplasmic antibody
○	Anti-streptolysin O antibody

This patient has features to suggest systemic lupus erythematosus (SLE) with antiphospholipid syndrome in this presentation, possibly due to renal vein thrombosis (flank pain with blood and protein in urine).

The diagnosis would be supported by the thrombocytopenia, history of hypertension and the livedo reticularis.

Wegener's with positive anti-neutrophil cytoplasmic antibody (ANCA) would be a less likely diagnosis.

Work Smart Session - MRCP Part 1

Question: 24 of 100

Which is the predominant site of effect of thiazide diuretics?

(Please select 1 option)

○	Cortical collecting duct
○	Early distal tubule
○	Late distal tubule
○	Proximal tubule
○	Thick ascending limb, Loop of Henle

Submit answer Skip question Tag Question Remove question

Work Smart Session - MRCP Part 1

Question: 24 of 100

Which is the predominant site of effect of thiazide diuretics?

(Please select 1 option)

○	Cortical collecting duct
◉	Early distal tubule ✓ Correct
○	Late distal tubule
○	Proximal tubule
○	Thick ascending limb, Loop of Henle

Thiazide diuretics act on the cortical diluting segment of the nephron, predominantly in the early distal tubule.

Loop diuretics mainly act on the thick ascending limb of the Loop of Henle.

Potassium sparing diuretics, for example amiloride, act on the distal nephron.

(For a simplistic review see ABC of heart failure.)

Work Smart Session - MRCP Part 1

Question: 25 of 100

An 18-year-old female student attends the clinic as her father has just died with end-stage renal failure. He had been diagnosed with autosomal dominant polycystic kidney disease (ADPKD).

She wishes to know what investigations she requires.

Which of the following is an appropriate strategy in her management?

(Please select 1 option)

○	Geneticist referral
○	Glomerular filtration rate estimation
○	MRI brain
◉	Ultrasound of the renal tract
○	Urine dipstick

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

○	Geneticist referral ← This is the correct answer
○	Glomerular filtration rate estimation
○	MRI brain
◉	Ultrasound of the renal tract ✗ Incorrect answer selected
○	Urine dipstick

An ultrasound of the renal tract may not be appropriate at this patient's age, given that cysts may not become apparent until the age of 20.

Gross haematuria in ADPKD carries a poor prognosis however microscopic haematuria may be a complication.

Subarachnoid haemorrhage may be a cause of mortality in 9% of patients with ADPKD, though 8% of patients have an asymptomatic intracranial aneurysm; if the diagnosis is confirmed and there is a strong history of subarachnoid haemorrhage then an MRI would be indicated.

Genetic counselling is most appropriate in this context and genetic linkage analysis may be utilised.

Time taken: 3 hrs 9 mins 10 secs

Work Smart Session - MRCP Part 1

Question: 26 of 100

A 34-year-old female presents with shortness of breath. She has been treated for asthma by her GP with an inhaled steroid, but the GP has documented an eosinophilia of 1.1 x 10^9/L (14%) (Normal <0.1 x 10^9/L). She has been referred to the clinic because her GP found her creatinine to be 347 µmol/l (60-110µmol/l).

Which of the following would support a diagnosis of Churg-Strauss syndrome?

(Please select 1 option)

- ○ Extravascular eosinophils on vascular biopsy
- ◉ Fixed pulmonary infiltrates on chest radiographs
- ○ Peak flow <150ml/minute
- ○ Peripheral alveolar filling infiltrate predominantly in the upper lobes on a chest radiograph
- ○ Peripheral "stocking" neuropathy

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

○	Extravascular eosinophils on vascular biopsy ← This is the correct answer
◉	Fixed pulmonary infiltrates on chest radiographs ✕ Incorrect answer selected
○	Peak flow <150ml/minute
○	Peripheral alveolar filling infiltrate predominantly in the upper lobes on a chest radiograph
○	Peripheral "stocking" neuropathy

- A diagnosis of Churg-Strauss syndrome requires four of the following features:
-
- asthma
- eosinophilia greater than 10%
- mononeuropathy or polyneuropathy
- paranasal sinus abnormality
- non-fixed pulmonary infiltrates visible on chest radiographs and
- blood vessels with extravascular eosinophils.
-
- Peripheral alveolar filling infiltrate predominantly in the upper lobes on a chest radiograph is typical of chronic eosinophilic pneumonia.
-
- A peripheral "stocking and glove" neuropathy is not typical of Churg-Strauss syndrome and is more common in Type 2 diabetes.

Time taken: 3 hrs 10 mins 52 secs

Work Smart Session - MRCP Part 1

Question: 27 of 100

A 62-year-old man with type 2 diabetes for 10 years attends for his annual review.His home blood glucose levels are 7-10 pre-breakfast, he remains overweight despite following his diet and being regularly active. Unfortunately he still smokes 10 cigarettes a day. His medication includes metformin 850 mg TDS, gliclazide 160 mg BD, simvastatin 40 mg OD, aspirin 75 mg OD, ramipril 10 mg OD. On examination his blood pressure is 145/85 mmHg with a BMI of 31.2. He has background diabetic retinopathy, with a distal sensory neuropathy. Recent bloods include a creatinine of 154micromol/l, and an HbA1c of 8.4%.

What is the appropriate intervention?

(Please select 1 option)

- Add insulin glargine to current treatment
- Add Novorapid TDS and insulin glargine
- Add pioglitazone 30 mg/day
- Stop gliclazide and metformin and use insulin glargine
- Stop metformin and commence insulin glargine

Submit answer | Skip question | Tag Question | Remove question

A 62-year-old man with type 2 diabetes for 10 years attends for his annual review.His home blood glucose levels are 7-10 pre-breakfast, he remains overweight despite following his diet and being regularly active. Unfortunately he still smokes 10 cigarettes a day. His medication includes metformin 850 mg TDS, gliclazide 160 mg BD, simvastatin 40 mg OD, aspirin 75 mg OD, ramipril 10 mg OD. On examination his blood pressure is 145/85 mmHg with a BMI of 31.2. He has background diabetic retinopathy, with a distal sensory neuropathy. Recent bloods include a creatinine of 154micromol/l, and an HbA1c of 8.4%.

What is the appropriate intervention?

(Please select 1 option)

○	Add insulin glargine to current treatment
○	Add Novorapid TDS and insulin glargine
○	Add pioglitazone 30 mg/day
○	Stop gliclazide and metformin and use insulin glargine
◉	Stop metformin and commence insulin glargine ✓ Correct

This patient has diabetic nephropathy as evidenced by proteinuria, hypertension and elevated creatinine.Current practice recommends the discontinuation of metformin if there is evidence of a reduced glomerular filtration rate, evidenced by a creatinine of greater than 130 µmol/l or eGFR less than 60 ml/min/1.73m^2. Therefore metformin should be stopped; this will lead to inevitable decline in overall diabetic control, which will need insulin therapy, which can be used alongside the sulphonylurea gliclazide.The use of pioglitazone is relatively contraindicated given the renal impairment because of the risk of associated fluid retention.

A 37-year-old woman underwent a kidney transplant which never functioned.

A biopsy revealed pathological features consistent with acute rejection associated with anti-HLA antibodies.

Which type of immunoglobulin is expected to account for this process?

(Please select 1 option)

○	Ig A
○	Ig D
○	Ig E
◉	Ig G ✓ Correct
○	Ig M

This acute rejection is recognised and due to anti-IgG antibodies to the human leukocyte antigen (HLA) incompatible tissues with primary activation of T cells.

The acute response is treated with immunosuppressants.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 35-year-old man presents with left loin pain and haematuria. He comments that he has had three episodes of similar symptoms in the past.

On examination, he is afebrile and has mild pallor.

Investigations show:

Sodium	140 mmol/L (137-144)
Potassium	3.0 mmol/L (3.5-4.9)
Chloride	115 mmol/L (95-107)
Bicarbonate	12 mmol/L (20-28)
Calcium	2.5 mmol/L (2.2-2.6)
Urea	19 mmol/L (2.5-7.5)
Urinalysis	pH 6.5, protein 1+, RBC 1+, White cell count 1+

What is the most likely diagnosis?

(Please select 1 option)

○	Bartter's syndrome
○	Conn's syndrome
○	Renal tubular acidosis type 1
○	Renal tubular acidosis type 2
○	Renal tubular acidosis type 4

Urinalysis	pH 6.5, protein 1+, RBC 1+, White cell count 1+

What is the most likely diagnosis?

(Please select 1 option)

○	Bartter's syndrome
◉	Conn's syndrome ✕ Incorrect answer selected
○	Renal tubular acidosis type 1 ← This is the correct answer
○	Renal tubular acidosis type 2
○	Renal tubular acidosis type 4

The patient has metabolic acidosis with failure appropriately to acidify the urine, pointing to a diagnosis of renal tubular acidosis (RTA).

Type 1 RTA is due to distal tubule defect to excrete hydrogen ions whereas type 2 RTA is associated with proximal tubule defect to reabsorb bicarbonate.

Type 1 is associated with nephrocalcinosis.

Both type 1 and 2 are associated with hypokalaemia whereas type 4 is characterised by hyperkalaemia.

Bartter's and Conn's syndromes are causes of hypokalaemia and metabolic alkalosis.

Remove Tag Remove question

Question: 2 of 100

A 63-year-old woman is admitted to hospital with a three day history of diarrhoea and vomiting. Her family tell you she has been virtually unable to eat or drink, but has managed to take her tablets during that time. Her past medical history includes essential hypertension and ischaemic heart disease. Her current medication consists aspirin 75 mg daily, ramipril 5 mg daily, simvastatin 40 mg daily. Her admission bloods demonstrate: sodium 144, potassium 4.1, urea 10.8, creatinine 195.

Which of the following is most appropriate?

(Please select 1 option)

○	Give clopidogrel 300 mg stat
◉	Withhold ramipril ✓ Correct
○	Double dose of ramipril
○	Give loperamide
○	Withhold aspirin

The history is entirely consistent with gastroenteritis, and as a result of the protracted vomiting the patient has become dehydrated. In this context an ACE inhibitor (ramipril) is dangerous and should be stopped.

Within the kidneys the afferent and efferent arterioles take blood to (afferent) and from (efferent) the glomerulus. ACE inhibitors work by decreasing the tone of the efferent arterioles, which in a euvolaemic patient can protect the kidney in hypertension, diabetes and other insults. However in a hypovolaemic patient (such as this patient) this can lead to catastrophic impairment of renal function.

Question: 3 of 100

A 22-year-old woman who is taking long term doxycycline for severe acne comes to the clinic complaining of chronic thirst and polyuria. She has to pass urine two to three times per night, which is highly unusual for her.

There is no significant past medical history, and her only medication is the oral contraceptive pill.

On examination her lying BP is 136/80 mmHg, with a postural drop of 15 mmHg. Her BMI is 29. There were no other significant findings on physical examination.

Investigations show

Haemoglobin	13.8 g/dl	(11.5-16.5)
White cells	6.3 x 10^9/l	(4-11)
Platelets	222 x 10^9/l	(150-400)
Sodium	141 mmol/l	(135-146)
Potassium	4.8 mmol/l	(3.5-5)
Creatinine	122 µmol/l	(79-118)
Urea	8.5 mmol/l	(2.5-6.7)

Which of the following is the most appropriate treatment?

(Please select 1 option)

- ○ Discontinue the doxycycline
- ○ Fluid restrict her
- ○ Increase her oral fluid intake
- ○ Intranasal vasopressin
- ○ Oral bendroflumethiazide

A 28-year-old female is referred with a three month history of tiredness and weakness.

On examination, pulse is 82 bpm and blood pressure is 128/72 mmHg. No specific abnormalities are evident on examination of the cardiovascular, respiratory, abdominal or neurological systems.

Investigations reveal:

Serum sodium	142 mmol/l	(137-144)
Serum potassium	3.0 mmol/l	(3.5-4.9)
Serum urea	4.2 mmol/l	(2.5-7.5)
Serum creatinine	82 µmol/l	(60-110)
Serum chloride	73 mmol/l	(95-107)
Plasma glucose	5.5 mmol/l	(3.0-6.0)
Urinary chloride	60 mmol/l	(20-350)

Which of the following is the likely diagnosis?

(Please select 1 option)

○	Bartter's syndrome
○	Conn's syndrome
○	Drug ingestion
○	Liddle's syndrome
○	Non-classical congenital adrenal hyperplasia (CAH)

Which of the following is the likely diagnosis?

(Please select 1 option)

○	Bartter's syndrome
○	Conn's syndrome
◉	Drug ingestion ✓ Correct
○	Liddle's syndrome
○	Non-classical congenital adrenal hyperplasia (CAH)

This young woman has hypokalaemia and hypochloraemia.

The normal blood pressure would exclude a diagnosis of Conn's, CAH, or Liddle's syndrome (apparent mineralocorticoid excess). Similarly, drug ingestion associated with hypokalaemia liquorice/carbenoxolone is associated with hypertension (and low urinary chloride less than 20 mmol/l).

Bartter's syndrome is a rare, recessive condition associated with weakness, lethargy and growth retardation and is found in youngsters. Hypokalaemic hypochloraemic alkalosis is seen in the condition but symptoms would be more apparent at a much younger age than this woman.

If Gitelman's syndrome were offered then that would be a better option.

Therefore the most likely diagnosis as the symptoms have arisen only over the last three months and no other features are apparent on examination, is diuretic abuse.

Work Smart Session - MRCP Part 1

Question: 31 of 100

A 32-year-old female is diagnosed with Goodpasture's syndrome.

Which of the following therapies used in conjunction with plasmapheresis and corticosteroids would be expected to improve prognosis associated with the condition?

(Please select 1 option)

- Azathioprine
- Cyclophosphamide
- Cyclosporin
- Mycophenolate mofetil
- Tacrolimus

Submit answer | Skip question | Remove question

Question: 31 of 100

A 32-year-old female is diagnosed with Goodpasture's syndrome.

Which of the following therapies used in conjunction with plasmapheresis and corticosteroids would be expected to improve prognosis associated with the condition?

(Please select 1 option)

○	Azathioprine
◉	Cyclophosphamide ✓ Correct
○	Cyclosporin
○	Mycophenolate mofetil
○	Tacrolimus

Studies reveal that without treatment mortality is as high as 90% in association with Goodpasture's.

However the prognosis is drastically improved with the removal of antigen through plasmapheresis, immunosuppression with corticosteroids and cyclophosphamide.

There are some studies revealing the potential of mycophenolate mofetil but the evidence is rather anecdotal.

Work Smart Session - MRCP Part 1

Question: 32 of 100

A 7-year-old boy is admitted with renal colic due to renal calculus.

His mother has a similar history of recurrent calculi.

What is the most likely explanation for recurrent renal calculi in both mother and child?

(Please select 1 option)

○	Cystinosis
○	Cystinuria
○	Hyperoxaluria
○	Idiopathic hypercalciuria
○	Urate uropathy

Submit answer | Skip question | Remove question

Question: 32 of 100

A 7-year-old boy is admitted with renal colic due to renal calculus.

His mother has a similar history of recurrent calculi.

What is the most likely explanation for recurrent renal calculi in both mother and child?

(Please select 1 option)

○	Cystinosis
◉	Cystinuria ✕ Incorrect answer selected
○	Hyperoxaluria
○	Idiopathic hypercalciuria ← This is the correct answer
○	Urate uropathy

Idiopathic hypercalciuria has a familial or sporadic pattern. In the familial pattern an autosomal dominant inheritance is present.

The type of the disease is identical in affected members of the same family and the typical presentation is of recurrent urinary calculi.

Cystinuria, cystinosis, urate uropathy and hyperoxaluria are autosomal recessive conditions.

Work Smart Session - MRCP Part 1

Question: 33 of 100

A 30-year-old female presents with fevers and a three month history of malaise.

Results show:

Creatinine	250 µmol/L (60-110)
Complement C3	23 mg/dL (65-190)

What is the likely diagnosis?

(Please select 1 option)

- HIV nephropathy
- Infective endocarditis
- Membranous nephropathy
- Microscopic polyangiitis
- Minimal change nephropathy

Submit answer | Skip question | Tag Question | Remove question

Creatinine	250 µmol/L (60-110)
Complement C3	23 mg/dL (65-190)

What is the likely diagnosis?

(Please select 1 option)

○	HIV nephropathy
◉	Infective endocarditis ✓ Correct
○	Membranous nephropathy
○	Microscopic polyangiitis
○	Minimal change nephropathy

Hypocomplementaemia is associated with either vasculitides such as systemic lupus erythematosus and cryoglobulinaemia but is also associated with a non-vascultic process such as subacute bacterial endocarditis (SBE).

In this case with the three month history and fevers SBE is suggested.

In microscopic polyangiitis, which is classically small vessel, complement would be expected to be normal.

Work Smart Session - MRCP Part 1

Question: 34 of 100

A 32-year-old male with type 1 diabetes undergoes a 24 hour urine collection.

Which of the following urine albumin concentrations signify microalbuminuria?

(Please select 1 option)

○	10 mg/day
○	50 mg/day
○	500 mg/day
○	1 g/day
○	3.5 g/day

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which of the following urine albumin concentrations signify microalbuminuria?

(Please select 1 option)

○	10 mg/day
◉	50 mg/day ✓ Correct
○	500 mg/day
○	1 g/day
○	3.5 g/day

Microalbuminuria is defined as a urine albumin excretion of between 30-300 mg per 24 hours.

A concentration above 300 mg/24 hours signifies albuminuria and a concentration above 3.5 g/24 hours signifies overt proteinuria.

Microalbuminuria is not just an indictor of early renal involvement but it also identifies increased cardiovascular risk with an approximate two- fold cardiovascular risk above the already increased risk in the diabetic population.

A useful surrogate of the total albumin excretion is the albumin: creatinine ratio. The urinary albumin:creatinine ratio is measured using the first morning urine sample where practicable.

Microalbuminuria is indicated where there is an albumin:creatinine ratio ≥2.5 mg/mmol (men) or 3.5 mg/mmol (women).

Proteinuria is indicated by a ratio of ≥30 mg/mmol.

Work Smart Session - MRCP Part 1

Question: 36 of 100

A 16-year-old girl developed pulmonary haemorrhage and acute renal failure requiring dialysis.

Investigations revealed:

Renal biopsy	Crescentic glomerulonephritis

Which one of the following antibodies is most likely to be found in the blood?

(Please select 1 option)

- Anticardiolipin
- Anticentromere
- Antimitochondrial
- Antimyeloperoxidase
- Antinuclear

Submit answer | Skip question | Tag Question | Remove question

Which one of the following antibodies is most likely to be found in the blood?

(Please select 1 option)

○	Anticardiolipin
○	Anticentromere
○	Antimitochondrial
◉	Antimyeloperoxidase ✓ Correct
○	Antinuclear

This patient manifests a pulmonary renal syndrome which is most commonly due to an anti-neutrophil cytoplasmic antibody test (ANCA) positive vasculitis and less commonly due to Goodpasture's syndrome (anti-glomerular basement membrane [GBM] antibodies).

ANCA antibodies are of two types:

1. C-ANCA which correlates with anti-proteinase 3 antibodies (PR3)
2. P-ANCA which correlates with anti-myeloperoxidase antibodies. P-ANCA/MPO antibodies are highly sensitive and specific for rapidly progressive glomerulonephritis and haemorrhagic alveolar capillaritis.

Anti-mitochondrial antibodies are found in primary biliary cirrhosis.

Anti-centromere antibodies are found in CREST/scleroderma syndrome.

ANA and anti-cardiolipin antibodies are found in systemic lupus erythematosus (SLE) which is not a cause of pulmonary renal syndrome.

Question: 37 of 100

A 28-year-old man presented with hypertension.

On examination he had palpable kidneys and abdominal ultrasound shows bilaterally enlarged cystic kidneys.

Which one of the following conditions is most likely to be present in this patient?

(Please select 1 option)

- Mitral stenosis
- Nail dystrophy
- Polycythaemia
- Short stature
- Testicular atrophy

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 28-year-old man presented with hypertension.

On examination he had palpable kidneys and abdominal ultrasound shows bilaterally enlarged cystic kidneys.

Which one of the following conditions is most likely to be present in this patient?

(Please select 1 option)

○	Mitral stenosis
○	Nail dystrophy
◉	Polycythaemia ✓ Correct
○	Short stature
○	Testicular atrophy

The most likely diagnosis here is adult polycystic kidney disease, which is associated with valvular heart abnormalities, incompetence and aneurysms of the cerebral circulation.

However, it is also associated with excessive erythropoietin production and polycythaemia.

Work Smart Session - MRCP Part 1

Question: 38 of 100

A 17-year-old boy presented with a non-blanching rash over his legs, a swollen knee and painless frank haematuria.

Investigations revealed:

Serum creatinine	210 µmol/L (60-110)
Urine dipstick analysis: Blood	+++
Urine dipstick analysis: Protein	+
Urine culture	Negative
Ultrasound of the kidneys	Normal

Which glomerular abnormality is most likely to be present at renal biopsy?

(Please select 1 option)

- ○ Focal and segmental sclerosis
- ○ Foot process fusion
- ○ Linear deposition of IgG on the basement membrane
- ○ Mesangial deposition of IgA
- ○ Thickening of basement membranes

Urine culture	Negative
Ultrasound of the kidneys	Normal

Which glomerular abnormality is most likely to be present at renal biopsy?

(Please select 1 option)

○	Focal and segmental sclerosis
○	Foot process fusion
○	Linear deposition of IgG on the basement membrane
◉	Mesangial deposition of IgA ✓ Correct
○	Thickening of basement membranes

The likely diagnosis here is Henoch-Schonlein purpura (HSP).

HSP is an inflammatory disorder of unknown cause characterised by IgA-dominant immune complexes in smaller venules, capillaries and arterioles. It presents with purpura, arthritis (especially ankles and knees), abdominal pains, haematuria and proteinuria.

HSP is often associated with infectious agents such as group A *Streptococci* and *Mycoplasma*.

If there is progression to renal impairment then renal histopathology may include minimal change to severe glomerulonephritis that is indistinguishable from IgA nephropathy. However, mesangial Ig A deposits are the most typical features of HSP on renal biopsy.

Question: 39 of 100

A 70-year-old man was referred by his GP with difficulty in treating hypertension.

He had longstanding hypertension which had been well controlled over many years but recently he was found to have a blood pressure of 190/110 mmHg which proved resistant to additional treatment.

He was generally asymptomatic and complied with medication. Investigations showed normal U+Es.

Which one of the following is the most likely cause?

(Please select 1 option)

- ○ Chronic pyelonephritis
- ○ Conn's syndrome (primary hyperaldosteronism)
- ○ Phaeochromocytoma
- ○ Polycystic kidney disease
- ○ Renovascular disease

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 70-year-old man was referred by his GP with difficulty in treating hypertension.

He had longstanding hypertension which had been well controlled over many years but recently he was found to have a blood pressure of 190/110 mmHg which proved resistant to additional treatment.

He was generally asymptomatic and complied with medication. Investigations showed normal U+Es.

Which one of the following is the most likely cause?

(Please select 1 option)

○	Chronic pyelonephritis
○	Conn's syndrome (primary hyperaldosteronism)
○	Phaeochromocytoma
○	Polycystic kidney disease
◉	Renovascular disease ✓ Correct

Primary hyperaldosteronism (Conn's syndrome) typically has hypokalaemic alkalosis.

One should also suspect Conn's with patients resistant to conventional antihypertensive treatment and with the electrolytes in the direction of Conn's without necessarily being outside the normal range (plasma Na > 140 and K < 4).

However, in this patient's case he has longstanding hypertension but has deteriorated. Therefore the most likely cause is renovascular disease related to his hypertension.

Next question

Tag Question | Remove question

Which of the following is the most appropriate treatment?

(Please select 1 option)

◉	Discontinue the doxycycline ✓ Correct
○	Fluid restrict her
○	Increase her oral fluid intake
○	Intranasal vasopressin
○	Oral bendroflumethiazide

Tetracyclines are known to be a cause of nephrogenic diabetes insipidus, as are

- Lithium
- Certain anti-fungals
- Certain anti-viral agents.

Whilst increasing her oral intake may relieve some of her symptoms of thirst, discontinuing the doxycycline is the only way to resolve both her thirst and her polyuria.

High dose intranasal vasopressin may relieve her symptoms but the most appropriate treatment is discontinuation of the tetracycline antibiotic.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 52-year-old man presents to the clinic having problems controlling his blood pressure, despite taking three anti-hypertensive agents, ramipril 10 mg, indapamide 2.5 mg, and amlodipine 5 mg.

Over the past few weeks he has been monitoring his BP at home and it is rarely below 155/90 mmHg.

On examination in the clinic his BP is 160/95 mmHg, his pulse is 85 and regular. He has a left carotid bruit. Respiratory and abdominal examinations are unremarkable.

Investigations show

Haemoglobin	12.0 g/dl	(13.5-17.7)
White cells	6.3 x 10^9/l	(4-11)
Platelets	200 x 10^9/l	(150-400)
Sodium	140 mmol/l	(135-146)
Potassium	4.8 mmol/l	(3.5-5)
Creatinine	182 µmol/l	(79-118)

Renal ultrasound scan showed significant size discrepancy, with the left kidney 2 cm smaller than the right.

Which of the following is the most appropriate next investigation?

(Please select 1 option)

- Contrast CT
- Duplex ultrasound scanning

Work Smart Session - MRCP Part 1

Question: 40 of 100

A 30-year-old woman becomes anuric 24 hours after a difficult laparoscopic cholecystectomy.

Investigations reveal:

Serum urea	9.2 mmol/l	(2.5-7.5)
Serum creatinine	120 micro mol/l	(60-110)

The blood pressure is 90/50 mmHg.

What is the next single most appropriate course of action in the management of the anuria?

(Please select 1 option)

- 1 L normal saline intravenously as fast as possible.
- Commence intravenous low-dose dopamine
- Give an 80 mg intravenous bolus of furosemide
- Give 500 ml intravenous plasma expander over 4 hours
- Urgent renal ultrasound

Submit answer | Skip question | Tag Question | Remove question

◉	1 L normal saline intravenously as fast as possible. ✓ Correct
○	Commence intravenous low-dose dopamine
○	Give an 80 mg intravenous bolus of furosemide
○	Give 500 ml intravenous plasma expander over 4 hours
○	Urgent renal ultrasound

This question is dealing with postoperative acute renal failure. This what you might find on the morning ward round and wonder why the problem was not picked up during the night.

Note that even when the glomerular filtration rate is zero, the serum creatinine tends not to rise faster than 200 micro mol/l per day - so the patient's creatinine of 120 micro mol/l may be the beginning of established renal failure.

Immediate management consists of restoring the circulation as quickly as possible; debate still continues whether it is better to use colloid or crystalloid.

In this case it would seem to be more appropriate to use 1 L of normal saline as the time scale for plasma expander is too long.

If urine output and renal function recover as soon as intravascular volume is restored, the diagnosis of pre-renal uraemia is made; if they do not then the diagnosis is acute tubular necrosis (ATN).

In a seemingly previously cardiovascularly-well 30-year-old with hypotension, giving 1 L over a short time will not precipitate any problems.

There is little evidence to suggest that loop diuretics and dopamine are effective in the treatment of ATN.

The next problem is to find out why the patient was hypotensive after surgery.....

Question: 41 of 100

A 30-year-old male presents with oedema and proteinuria.

On examination his blood pressure was 120/70 mmHg.

Investigations reveal:

Creatinine	88 µmol/L (60-110)
Albumin	25 g/L (37-49)
Urinalysis	No blood
Protein	++++
Urinary protein excretion	7g/24hr (<0.2)

- Ultrasound of renal tract normal right kidney, absent left kidney

Which is the most appropriate course of action for this patient?

(Please select 1 option)

○	Albumin transfusion
○	Angiotensin converting enzyme (ACE) inhibitor therapy
○	High protein diet
○	Renal biopsy
○	Trial of steroid therapy

http://my.onexamination.com/Assessment/Que
Questions Set : REF7559
passmedicine.com
passmedicine.com

○	Renal biopsy
◉	Trial of steroid therapy ✓ Correct

This patient has nephrotic syndrome, which is a combination of:

- Proteinuria (usually > 3g/24 hrs)
- Hypoalbuminaemia (<35g/L)
- Oedema
- Hyperlipidaemia.

The most appropriate course of action here would be to undergo a trial of steroid therapy.

Ideally a renal biopsy would be indicated to determine the cause of the nephrotic syndrome, however as this patient only has one kidney then this would be considered a relative contraindication for such a procedure.

A high protein diet / albumin transfusion would be of little to no benefit - and the latter would need to be salt poor.

ACE inhibitors reduce proteinuria and slow deterioration in glomerular filtration rate (GFR).

In this case given the patient's age he may well have minimal change glomerulonephritis (GN) (commonest in children), which is normally steroid responsive.

In the young adult histological diagnoses are in general: minimal change > mesangiocapillary > FSGS > lupus > membranous > diabetes.

In general steroids are tried first and then second line agents such as cyclosporin and cyclophosphamide are introduced if needed.

Work Smart Session - MRCP Part 1

Question: 42 of 100

A 25-year-old female wishes to start a family but she is concerned as her 50-year-old mother had adult polycystic kidney disease.

Examination reveals no specific abnormalities.

Which is the most appropriate screening test for polycystic kidney disease in this woman?

(Please select 1 option)

○	Genetic linkage analysis
○	Intravenous urogram
○	Isotope renography
○	Renal ultrasound
○	Urinalysis

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

EN 3:55 PM 3/1/2011

(Please select 1 option)

◉	Genetic linkage analysis ✕ Incorrect answer selected
○	Intravenous urogram
○	Isotope renography
○	Renal ultrasound ← This is the correct answer
○	Urinalysis

The answer lies between renal ultrasound and genetic linkage analysis. Polycystic kidney disease is an autosomal dominant disorder. Mutations in at least three different genes can lead to autosomal dominant polycystic disease (APKD).

1. PKD-1 on chromosome 16: 85% of cases. Polycystin 1 is an integral membrane glycoprotein involved in cell/matrix interactions
2. PKD-2 on chromosome 4: 10% of cases. Polycystin 2 which may associate with polycystin 1 through a common signalling pathway
3. A third gene mutation is known but its exact chromosomal location is not.

Diagnosis is made by multiple bilateral renal cysts and a positive family history.

Genetic linkage studies: Can exclude or make the diagnosis in younger patients. Requires blood from at least two affected family members.

Ultrasonography:

- In PKD 1 families, age related diagnostic criteria are used: two cysts in under 30 years age group.
- At least two cysts in each kidney in 30-59 years. Four cysts in each kidney for over 60 years.

CT: More sensitive than USS and may aid in diagnosis in younger patients.

MR angiography: In patients with a family history of intracranial aneurysm - to screen for cerebral aneurysms.

Work Smart Session - MRCP Part 1

Question: 43 of 100

A 60-year-old male presents with typical renal colic and one day later passes a small stone.

However, the original x ray of the abdomen revealed no obvious calculi.

What is the most likely composition of his calculus?

(Please select 1 option)

- Calcium
- Cystine
- Oxalate
- Phosphate
- Uric acid

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

What is the most likely composition of his calculus?

(Please select 1 option)

○	Calcium
◉	Cystine ✗ Incorrect answer selected
○	Oxalate
○	Phosphate
○	Uric acid ← This is the correct answer

The main constituent will be uric acid.

Major causes of stone formation:

- Calcium stones (80%) - hypercalciuria (for example, primary hyperparathyroidism), hyperoxaluria (for example, XS intake, ileal disease and bypass)
- Uric acid stones (10%) - high purine intake, high cell turnover
- Cystine stones (2%) - cystinuria (AR defect in dibasic amino acid transporter)
- Infection stones (5%) - chronic infection with urea splitting organisms causes stones made of magnesium ammonium phosphate and calcium phosphate
- Other stones (3%) - include xanthine stones, rare renal chloride channel mutations can cause stone formation.

There appears to be a male predominance with a 2:1 ratio.

Calcium and infection stones are radio-opaque, cystine stones are weakly radio-opaque and urate stones are radiolucent.

Time taken: 4 hrs 33 secs

Work Smart Session - MRCP Part 1

Question: 44 of 100

A 45-year-old man presented to the nephrology clinic with severe generalised oedema.

Investigations showed:

Serum albumin	20 g/L (37-49)
24-hour urinary protein excretion	14.6 g (<0.2 g)
Renal biopsy	Normal on light microscopy, normal on immunoflorescence

There was no significant improvement in his symptoms or signs after three months treatment with prednisolone 60 mg OD.

What is the most likely diagnosis?

(Please select 1 option)

- ○ Focal segmental glomerulosclerosis
- ○ Membranous nephropathy
- ○ Minimal change disease
- ○ Myeloma
- ○ Renal vein thrombosis

◉	Minimal change disease ✓ Correct
○	Myeloma
○	Renal vein thrombosis

This patient has symptoms and signs of a nephrotic syndrome. A renal biopsy was normal on light microscopy and immunofluorescence.

Focal segmental glomerulosclerosis and membranous nephropathy are histological diagnoses. As this patient's renal biopsy was normal he cannot have these diagnoses.

Myeloma generally causes a cast nephropathy, but can also cause

- Fanconi syndrome
- Light chain amyloidosis
- Light chain deposition
- Infiltration of renal interstitium by plasma cells
- Calcium precipitation and
- Renal infection.

This may cause acute renal failure, chronic renal failure or nephrotic syndrome.

All the above lesions should be visible on light microscopy of the renal biopsy.

Renal vein thrombosis is an uncommon cause of the nephrotic syndrome. It is not normally associated with such heavy proteinuria and if it is, there are usually changes seen on microscopy.

The likely diagnosis is minimal change nephropathy. Although it is more common in children it does occur in adults and is then associated with poorer outcomes. As well as heavy proteinuria oval fat bodies may also be seen in the urine.

Time taken: 4 hrs 3 mins 19 secs

Work Smart Session - MRCP Part 1

Question: 45 of 100

A 45-year-old man with chronic renal failure presents to clinic complaining of increasing fatigue and weakness.

He receives three hours of haemodialysis, thrice weekly. His blood pressure is measured at 176/110 mmHg pre-dialysis and 166/95 mmHg post-dialysis.

Investigations pre-dialysis show:

Hb	9.5 g/d	(13.0-18.0)
Potassium	6.9 mmol/l	(3.5-4.9)
Creatinine	1567 µmol/l	(60-110)
Calcium	(corrected) 2.1 mmol/l	(2.2-2.6)

Which of the following options is most appropriate initial management for this patient?

(Please select 1 option)

- ○ Give alfacalcidol to correct hypocalcaemia
- ○ Increase the duration of each dialysis session
- ○ Reduce the potassium concentration in the dialysate
- ○ Start erythropoietin to increase haemoglobin level
- ○ Start ramipril to gain better control of his blood pressure

◉	Increase the duration of each dialysis session ✓ Correct
○	Reduce the potassium concentration in the dialysate
○	Start erythropoietin to increase haemoglobin level
○	Start ramipril to gain better control of his blood pressure

This patient has been poorly managed! Again the question is the issue here. What is the most appropriate management in this case?

Pre-dialysis blood pressure and blood investigations are a poor indication of dialysis adequacy. It would be more helpful in this question to have post-dialysis blood results, especially urea, which could give an idea of dialysis adequacy.

His post-dialysis blood pressure is too high. It should be controlled with antihypertensive medication if the patient is achieving his dry weight with fluid ultra filtration on haemodialysis.

His haemoglobin is lower than 11 g/dl, which is the minimum level a patient with end stage renal failure should have. Initially he should be treated with IV iron, and if the haemoglobin is still low, erythropoietin should be commenced.

Hyperkalaemia can cause lethargy and muscle weakness, but only if the levels are over 7 mmol/l. The above potassium level is probably expected pre-dialysis.

His corrected calcium is borderline low (aim for 2.2-2.6 mmol/l), but should not cause the above symptoms.

This patient has non-specific symptoms. He is hypertensive post-dialysis, and has a very high pre-dialysis serum creatinine. He requires further management of his haemoglobin, blood pressure and calcium levels.

None of the above would cause the non-specific deterioration seen in this patient, and therefore the most appropriate management strategy that would affect most things would be increasing the dialysis adequacy, by increasing the duration of each dialysis session.

A 14-year-old old boy presents with a sore throat and macroscopic haematuria.

What would light microscopy of a kidney biopsy most likely show?

(Please select 1 option)

○	Collapsed glomeruli
○	Crescentic glomerulonephritis
◉	Mesangial hypercellularity ✓ Correct
○	Normal tissue
○	Segmental sclerosis

The most common cause of macroscopic haematuria in a child is IgA nephritis.

This usually develops one to two days after a sore throat. It is most common in the second and third decades of life and is three times more common in males.

The urine may be frankly bloody or may be the colour of cola. There are no clots in the urine and the haematuria is generally painless although some patients complain of mild loin pain.

It tends to settle spontaneously within five days although the episodes may be recurrent lasting for one to two years.

Renal biopsy will show mesangial IgA deposition on immunofluorescence and light microscopy will show mesangial hypercellularity and matrix expansion.

Work Smart Session - MRCP Part 1

Question: 47 of 100

A 62-year-old man with a longstanding history of hypertension is seen in the outpatient clinic.

Investigations show:

Creatinine	280 µmol/L (60-110)

Urinalysis

Blood	++
Protein	1.8 g/L

- Ultrasound scan of kidneys left kidney 8.5 cm; right kidney 8.9 cm

What is the best investigation to diagnose the cause of his renal impairment?

(Please select 1 option)

- ○ Intravenous urogram (IVU)
- ○ Isotope renogram
- ○ Renal angiogram
- ○ Renal biopsy
- ○ Retrograde pyelogram

Protein	1.8 g/L

- Ultrasound scan of kidneys left kidney 8.5 cm; right kidney 8.9 cm

What is the best investigation to diagnose the cause of his renal impairment?

(Please select 1 option)

○	Intravenous urogram (IVU)
○	Isotope renogram
◉	Renal angiogram ✕ Incorrect answer selected
○	Renal biopsy ← This is the correct answer
○	Retrograde pyelogram

This patient has a long history of hypertension, therefore it should have been appropriately controlled in the clinic.

The patient now presents with bilaterally shrunken kidneys, renal impairment and evidence of a glomerulonephritis.

In the presence of mild to moderate hypertension, proteinuria indicates either underlying renal disease or renovascular disease.

As this patient has blood and protein in the urine, on the background of impaired renal function and shrunken kidneys, the best investigation would be to perform a renal biopsy (assuming the hypertension was controlled). This would differentiate between renovascular disease and glomerulonephritis, which may be reversible.

If this patient had the above clinical findings without blood and protein in the urine, then the investigation of choice would be a renal angiogram, to diagnose renovascular disease.

Time taken: 4 hrs 8 mins 43 secs

Work Smart Session - MRCP Part 1

Question: 48 of 100

A 16-year-old girl presented to the nephrology clinic with a four-day history of steadily increasing generalised oedema. There was no past history of note.

On examination she weighed 45kg. Her blood pressure was 90/55 mmHg.

Investigations revealed:

Serum creatinine	55 µmol/L (60-110)
Serum albumin	20 g/L (37-49)

- 24 hour urinary protein excretion 4.8g (<0.2g)
- Ultrasound scan of kidneys normal

If this patient is treated with prednisolone (1mg/kg for six weeks), what are the chances of her disease going into complete remission?

(Please select 1 option)

○	<20%
○	20 – 39%
○	40 – 59%
○	60 – 80%
○	>80%

If this patient is treated with prednisolone (1mg/kg for six weeks), what are the chances of her disease going into complete remission?

(Please select 1 option)

○	<20%
○	20 – 39% ← This is the correct answer
○	40 – 59%
◉	60 – 80% ✕ Incorrect answer selected
○	>80%

This girl has probably developed idiopathic glomerulonephritis, which accounts for 90% of all childhood cases of the nephrotic syndrome. The main cause is minimal change nephrotic syndrome.

The first line treatment for minimal change nephropathy is prednisolone for four to six weeks (60mg/m^2) reducing to 40mg/m^2 for a further four to six weeks.

With this treatment 93% of children will respond with complete loss of proteinuria within eight weeks.

However, once remission is induced, 66% of children will have at least one relapse (34% will have complete remission).

Between 40 and 55% of children affected, who initially respond to steroids, will develop multiple relapses when the steroids are reduced.

Early, frequent relapses (three or more in the first six months) signify a relapsing course which requires treatment with cyclophosphamide.

Time taken: 4 hrs 10 mins 22 secs

Work Smart Session - MRCP Part 1

Question: 49 of 100

A 70-year-old woman was referred with a six-week history of painless macroscopic haematuria.

Her only medications were IM sodium aurothiomalate and oral ibuprofen, which she took for rheumatoid arthritis.

Investigations:

Serum creatinine	92 mol/L (60-110)
Urine dipstick	Blood++++
Protein	+

- Abdominal plain x ray normal
- Ultrasound kidneys and renal tract normal

Which one of the following is the best initial investigation?

(Please select 1 option)

○	Cystoscopy
○	Intravenous urogram (IVU)
○	Renal biopsy
○	Stop ibuprofen
○	Stop sodium aurothiomalate

Protein	+

- Abdominal plain x ray normal
- Ultrasound kidneys and renal tract normal

Which one of the following is the best initial investigation?

(Please select 1 option)

◉	Cystoscopy ✓ Correct
○	Intravenous urogram (IVU)
○	Renal biopsy
○	Stop ibuprofen
○	Stop sodium aurothiomalate

This lady has macroscopic haematuria and a trace of protein in the urine. She is taking ibuprofen and IM sodium aurothiomalate (gold). Her renal function is normal, as is the plain abdominal x ray and USS renal tract.

Ibuprofen is a common cause of interstitial nephritis, and this could present with painless haematuria.

Sodium aurothiomalate commonly causes trace proteinuria, and if present on its own is unimportant, but it can also cause membranous glomerulonephritis, which this lady could have.

However. the most important thing to exclude would be a bladder tumour initially before embarking upon a renal biopsy. Therefore cystoscopy is the best initial investigation.

A 62-year-old woman presents with severe nausea and lethargy a few days after beginning diclofenac and amoxicillin from her GP for pain and a urinary tract infection. She has no past history of note apart from hypertension for which she takes ramipril, and she believes she injured her back lifting a wardrobe.

On examination her BP is 159/92 mmHg, she has bilateral crackles on auscultation of the chest, her pulse is 89 and regular. Abdominal examination is unremarkable. She has a widespread erythematous rash.

Investigations show

Hb	11.9 g/dl	(13.5-18)
WCC	8.9 x 10^9/l Eosinophilia	(4-11)
PLT	203 x 10^9/l	(150-400)
Na	139 mmol/l	(135-146)
K	6.1 mmol/l	(3.5-5)
Cr	382 mmol/l	(79-118)
Urine protein	++	
Blood	-	
White cells	-	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- Acute tubular necrosis
- Churg-Strauss syndrome
- Interstitial nephritis
- Membranous nephropathy
- Pyelonephritis

Work Smart Session - MRCP Part 1

Question: 50 of 100

Which of the following is least true regarding IgA nephropathy?

(Please select 1 option)

○	Commonly follows a sore throat
○	Is the most common glomerulonephritis in the world
◉	Light chains may be found in the urine ✓ Correct
○	May be associated with a rash and arthritis
○	Predominantly affects young men

IgA nephropathy (Berger's disease) is the most common glomerulonephritis worldwide and characteristically affects young males, presenting with frank haematuria after an episode of pharyngitis.

However it may also present with proteinuria, microscopic haematuria, renal failure or hypertension.

It is probably part of a spectrum of disease with Henoch-Schonlein purpura, which presents with arthritis, rash, abdominal pain and nephritis. In both there are mesangial IgA deposits in the kidney.

Question: 51 of 100

A 16-year-old female presents with ankle swelling four days after having had a sore throat. On examination she had a blood pressure of 125/80 mmHg and ankle oedema. Investigations reveal:

Creatinine	90 µmol/l	(60-110)
Albumin	25 g/l	(37-49)
24 hour urinary protein	9 g	(<0.2)

What is the most likely diagnosis?

(Please select 1 option)

- Idiopathic membranous nephropathy
- IgA nephropathy
- Membranoproliferative glomerulonephritis
- Minimal change nephropathy
- Post-streptococcal glomerulonephritis

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Idiopathic membranous nephropathy
○	IgA nephropathy ← This is the correct answer
○	Membranoproliferative glomerulonephritis
◉	Minimal change nephropathy ✕ Incorrect answer selected
○	Post-streptococcal glomerulonephritis

Idiopathic membranous nephropathy (option A) accounts for 2-5% of cases of nephritic syndrome in children, and 20-30% of cases in adults.

The immune mechanism that leads to the development of membranous nephropathy is unknown. Histologically, it is characterised by diffuse thickening of the glomerular basement membrane (GBM) on light microscopy. On immunofluorescence, the thickening is caused by immune deposits of IgG and C3, on the subepithelial surface of the GBM.

When not idiopathic, it is associated with

- AI diseases (SLE, rheumatoid arthritis, thyroid disease)
- drugs (gold, penicillamine, captopril)
- malignancy (bronchus, breast, stomach, colon, prostate)
- infections (hep B, syphilis, leprosy, filariasis)
- diabetes mellitus.

Membranoproliferative (or mesangiocapillary) glomerulonephritis (option C) can be classed into three types (I, II, and III) depending on which complement pathway is activated. It is associated with SLE, cryoglobulinaemia with or without hep C, chronic infections (SBE) or with neoplasms. It is not associated acutely with upper respiratory tract infections.

Minimal change nephropathy (option D) is the most common form of nephrotic syndrome in children. The histological findings on light

(SBE) or with neoplasms. It is not associated acutely with upper respiratory tract infections.

Minimal change nephropathy (option D) is the most common form of nephrotic syndrome in children. The histological findings on light microscopy are normal or small looking glomeruli. On electron microscopy there is effacement of the epithelial cell foot processes over the outer surface of the GBM. It tends to be steroid responsive in children, but over 60% of children will have further relapses. In adults, it is associated with Hodgkin's lymphoma, and other carcinomas.

Post streptococcal GN (option E), as the name implies, occurs 10-14 days after an acute infection. The typical case occurs following infection with group A Lancefield streptococci (β-haemolytic strep, *S. pyogenes*) either causing pharyngitis or skin infections. It is more common in the developing world. The histology shows diffuse proliferative GN, with infiltration by neutrophil polymorphs. The main treatment is eradication of the infection (10/7 course of penicillin) and symptomatic relief of the acute nephritis. The need for dialysis is uncommon, and complete recovery of renal function should occur.

The correct answer is IgA nephritis (option B). IgA nephritis is most common during the second and third decade of life. It commonly occurs within two days of an onset of an upper respiratory tract infection, or less commonly infection of other mucous membranes (e.g. GI, bladder, breast). It should be diagnosed by a renal biopsy, where IgA is seen deposited in the mesangium.

The treatment of IgA nephritis is variable. In a patient with haematuria only, the treatment is conservative. When there is nephrotic range proteinuria (>3 g/day - as in this case) an 8-12 week course of prednisolone should be prescribed. If the proteinuria is <3 g/day an ACE inhibitor can be used. In all patients, careful control of blood pressure should be achieved, by using ACE inhibitors in the first instance, and regular follow up of renal function and urinalysis.

30% of children will have a spontaneous remission within 10 years, but 25% will go on to develop ESRF within 20 years.

Work Smart Session - MRCP Part 1

Question: 52 of 100

A 21-year-old female presents with joint pains and rash. On examination her blood pressure was 140/100 mmHg.

Investigations reveal:

Creatinine	90 µmol/l	(60-110)
Anti dsDNA antibodies	Strongly positive	(0-73)
24 hour urinary protein excretion	1.7 g	(<0.2)
Renal biopsy	Membranous nephropathy	

What is the most appropriate next treatment?

(Please select 1 option)

- A. ACE inhibitor for blood pressure control
- B. Cyclophosphamide
- C. NSAIDs for arthralgia
- D. Prednisolone for immunosuppression
- E. Warfarin anticoagulation

Submit answer | Skip question | Tag Question | Remove question

What is the most appropriate next treatment?

(Please select 1 option)

○	A. ACE inhibitor for blood pressure control ← This is the correct answer
○	B. Cyclophosphamide
○	C. NSAIDs for arthralgia
◉	D. Prednisolone for immunosuppression ✕ Incorrect answer selected
○	E. Warfarin anticoagulation

This patient has systemic lupus erythematosus with the disease affecting her kidneys.

The biopsy has shown pure membranous nephropathy, classifying the disease as class V(a) on the 1995 WHO classification of lupus nephritis. Class V(a and b) have a low rate of progression to renal failure.

There is no clear consensus on treatment, but most nephrologists would start treatment with prednisolone. Cyclophosphamide could be added in later as a steroid sparing agent.

Warfarin is not considered an appropriate treatment as if this lady exhibited any prothrombotic tendencies (on the background of antiphospholipid antibody disease) she should be started on aspirin.

Non-steroidal anti-inflammatory medication would treat her arthralgia but would have no effect on the prognosis of the disease.

As there is a low rate of progression of renal disease in this patient the blood pressure should be aggressively treated with an angiotensin-converting enzyme (ACE) inhibitor and this could assist in reducing the proteinuria.

Therefore, the correct answer should be A, but closely followed by answer D.

Work Smart Session - MRCP Part 1

Question: 53 of 100

A 25-year-old woman who is 20 weeks pregnant is diagnosed with pyelonephritis.

She had suffered recurrent urinary infections since childhood and her family history reveals that her mother had a history of hypertension and had been told she had a kidney problem.

Examination was normal and urea and creatinine were both normal.

What is the most likely diagnosis?

(Please select 1 option)

- A. Autosomal dominant polycystic kidney disease
- B. Bladder outlet obstruction
- C. Normal physiological urinary stasis of pregnancy
- D. Reflux nephropathy
- E. Renal stone disease

Submit answer | Skip question | Tag Question | Remove question

What is the most likely diagnosis?

(Please select 1 option)

◉	A. Autosomal dominant polycystic kidney disease ✕ Incorrect answer selected
○	B. Bladder outlet obstruction
○	C. Normal physiological urinary stasis of pregnancy
○	D. Reflux nephropathy ← This is the correct answer
○	E. Renal stone disease

This lady has had recurrent urinary tract infections since childhood and now presents with pyelonephritis. Pyelonephritis is an uncommon infection in pregnancy and requires aggressive treatment with antibiotics. It is associated with preterm labour in 4% and may lead to fetal distress.

The answer is not ADPKD (A) as symptoms do not tend to occur before the age of 40.

Bladder outlet obstruction (B) should not occur in pregnancy and would cause hydronephrosis and worsening renal function.

Answer C is incorrect as this should not cause pyelonephritis.

Renal stone disease (E) does predispose to developing urinary tract infections but is less likely than reflux nephropathy.

The correct answer is reflux nephropathy (D). This lady has a long history of urinary tract infections with probable underlying reflux scarring and this would predispose her to developing pyelonephritis in pregnancy.

Work Smart Session - MRCP Part 1

Question: 54 of 100

A 65-year-old female is referred with a long history of hypertension and episodic urinary tract infections. Dipstick analysis of the urine shows Blood +++ together with protein +++. Her urea is 20 mmol/L (2.5-7.5) and creatinine is 280 µmol/L (60-110).

An ultrasound of abdomen is requested and shows left and right kidneys of 9 cm in size (10-12) without evidence of obstruction.

Which one of the following is the best investigation to diagnose the cause of her renal failure?

(Please select 1 option)

- A. Isotope renography
- B. IV urography
- C. Renal angiography
- D. Renal biopsy
- E. Retrograde pyelography

Submit answer | Skip question | Tag Question | Remove question

Help

Which one of the following is the best investigation to diagnose the cause of her renal failure?

(Please select 1 option)

○	A. Isotope renography
○	B. IV urography
○	C. Renal angiography
◉	D. Renal biopsy ✓ Correct
○	E. Retrograde pyelography

This patient has impaired renal function with hypertension and significant proteinuria and haematuria (? glomerulonephritis). The kidneys are smaller than expected with no evidence of obstruction.

Intravenous urography (B) is not the investigation of choice in a patient with impaired renal function.

Isotope renography (A) would provide information about the relative function of each kidney and would show areas of scarring due to renal stone disease, infection, or vascular disease. It would also exclude congenital malformations of the kidneys. Although useful it would not provide information on the cause of the haematuria and proteinuria.

Renal angiography (C) is the gold standard for assessing renovascular disease. It is an invasive procedure with potential complications. This investigation would not exclude causes of proteinuria and haematuria.

Retrograde pyelography (E) would be useful if there were any evidence of obstruction.

The best investigation is a renal biopsy. This would show any changes of glomerulonephritis along with renal scaring from longstanding hypertension or urinary tract infections.

Work Smart Session - MRCP Part 1

Question: 55 of 100

A 30-year-old woman receives a cadaveric renal transplantation after having had renal failure, with a neuropathic bladder for which she performed intermittent self-catheterisation.

Six months after transplantation she presents with acute pain in the region of the transplanted kidney.

Which one of the following is the most likely reason for the pain?

(Please select 1 option)

- Acute retention of urine
- Allograft rejection
- Pyelonephritis
- Renal calculi
- Renal infarction

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

unlikely occurrence.

Due to the elapsed time between the transplant and this episode, allograft rejection can be discounted. This is because chronic rejection (more than three months post transplant) is a painless process, with difficult to control hypertension, proteinuria and slowly rising serum creatinine.

Accelerated rejection (one to five days post transplant) can present with fever, an acutely tender swollen graft, and rapidly rising serum creatinine.

Acute rejection (five days to three months) is clinically silent in the majority, but can present with a swollen, tender kidney.

Renal infarction can also be discounted. This can be a surgical complication of renal transplantation, but it presents early with a calyceal fistula and urinary leak.

Renal stones could cause acute pain in the region of a transplanted kidney, but would be less likely in this patient than acute retention of urine.

The answer in this case is acute pyelonephritis.

This patient is in the intermediate stage of the post-transplantation immunosuppression, when the patient is most immunocompromised (three to six months post-transplant).

She is at high risk of an acute episode of pyelonephritis in the transplanted kidney, due to the immunosuppression, the neuropathic bladder and self-catheterisation. This would present like an acute rejection episode, with a tender swollen graft, low-grade pyrexia, and deteriorating graft function.

This would be commonly associated with septicaemia in this patient, and requires parenteral antibiotics.

If this lady were to be managed as a transplant rejection, with high dose intravenous steroids, the result could be catastrophic.

- Help

Which one of the following is the most likely reason for the pain?

(Please select 1 option)

○	Acute retention of urine
◉	Allograft rejection ✕ Incorrect answer selected
○	Pyelonephritis ← This is the correct answer
○	Renal calculi
○	Renal infarction

Acute urinary retention would not cause pain overlying a transplanted kidney, and as this lady self-catheterises, it would be an unlikely occurrence.

Due to the elapsed time between the transplant and this episode, allograft rejection can be discounted. This is because chronic rejection (more than three months post transplant) is a painless process, with difficult to control hypertension, proteinuria and slowly rising serum creatinine.

Accelerated rejection (one to five days post transplant) can present with fever, an acutely tender swollen graft, and rapidly rising serum creatinine.

Acute rejection (five days to three months) is clinically silent in the majority, but can present with a swollen, tender kidney.

Renal infarction can also be discounted. This can be a surgical complication of renal transplantation, but it presents early with a calyceal fistula and urinary leak.

Renal stones could cause acute pain in the region of a transplanted kidney, but would be less likely in this patient than acute retention of urine.

Work Smart Session - MRCP Part 1

Question: 56 of 100

A 70-year-old man is admitted to hospital complaining of a twelve day history of loin pain, fevers and occasional rigors. On examination, his temperature is 37.9°C. The renal function is normal.

Urinalysis of a mid stream urine shows:

White cell count	>100/mm^3
Red cell count	>50/mm^3

No organisms seen, with no growth.

Which would be your first investigation of choice?

(Please select 1 option)

- CT abdomen and pelvis
- Intravenous urogram (IVU)
- Prostatic specific antigen (PSA) measurement
- Transthoracic echocardiogram
- Ultrasound scan renal tract

○	Intravenous urogram (IVU)
○	Prostatic specific antigen (PSA) measurement
○	Transthoracic echocardiogram
◉	Ultrasound scan renal tract ✓ Correct

Renal cell carcinomas may present in a variety of ways, with only a minority being diagnosed with the classical triad of:

- haematuria
- loin pain
- a palpable mass.

Relatively common presentations include:

- anaemia
- hypertension
- pyrexia of unknown origin
- fatigue
- increased plasma viscosity.

Less common presentations include:

- hypercalcaemia
- polycythaemia
- liver dysfunction
- enteropathy

- liver dysfunction
- enteropathy
- myopathy.

Urinalysis may show sterile pyuria, as here.

Other causes of sterile pyuria are:

- partially treated urinary tract infections (UTI)
- tuberculosis (TB) of the renal tract
- urethritis and sexually transmitted diseases
- acute glomerulo-nephritis
- tubulo-interstitial diseases
- adult polycystic kidney disease
- renal stones.

Ultrasound scan of the renal tract would be the first investigation of choice, as it is able to pick up 95% of renal cell carcinomas greater than 1 cm in diameter. It would also exclude infective or inflammatory collections within the renal tract.

If required a computerised tomography (CT) +/- guided biopsy could be obtained to prove the diagnosis.

An intravenous urogram (IVU) was considered the investigation of choice before the advent of ultrasound.

A chest x ray and bone scan would be required to complete the basic investigations.

Work Smart Session - MRCP Part 1

Question: 57 of 100

A 42-year-old female with a recent diagnosis of systemic sclerosis, is referred to hospital with a complaint of headaches and blurred vision. She has a past medical history of asthma. On examination, her blood pressure is 230/120 mmHg and there is bilateral papilloedema.

Which of the following medications should be prescribed immediately?

(Please select 1 option)

○	IV furosemide
○	IV labetolol
○	IV sodium nitroprusside
○	Oral enalapril
○	Sublingual nimodipine

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	IV furosemide
○	IV labetolol
◉	IV sodium nitroprusside ✕ Incorrect answer selected
○	Oral enalapril ← This is the correct answer
○	Sublingual nimodipine

Systemic sclerosis is a systemic disorder characterised by skin thickening due to the deposition of collagen in the dermis. Adverse prognostic features are renal, cardiac or pulmonary involvement.

A major complication is the development of scleroderma renal crisis. This is characterised by the abrupt onset of severe hypertension, usually with retinopathy, together with rapid deterioration of renal function and heart failure. It develops in 8-15% of patients with diffuse systemic sclerosis especially associated with rapid progression of diffuse skin disease. It usually presents early, within three years of diagnosis. The pathogenic mechanisms leading to renal damage are not known.

The clinical presentation is typically with the symptoms of malignant hypertension

- Headaches
- Blurred vision
- Fits
- Heart failure.

Renal function is impaired and usually rapidly deteriorates. The hypertension is almost always severe with a diastolic BP over 100 mmHg in 90% of patients. There is hypertensive retinopathy in about 85% of patients with exudates and haemorrhages and if severe, papilloedema.

Scleroderma renal crisis is a medical emergency. The hypertension should be treated with an ACE inhibitor. The aim is to reduce the blood pressure gradually as an abrupt fall can lead to cerebral ischaemia or infarctions (as in any accelerated hypertension). Calcium

○	Oral enalapril ← This is the correct answer
○	Sublingual nimodipine

Systemic sclerosis is a systemic disorder characterised by skin thickening due to the deposition of collagen in the dermis. Adverse prognostic features are renal, cardiac or pulmonary involvement.

A major complication is the development of scleroderma renal crisis. This is characterised by the abrupt onset of severe hypertension, usually with retinopathy, together with rapid deterioration of renal function and heart failure. It develops in 8-15% of patients with diffuse systemic sclerosis especially associated with rapid progression of diffuse skin disease. It usually presents early, within three years of diagnosis. Scleroderma renal crisis is a medical emergency. The hypertension should be treated with an ACE inhibitor. The aim is to reduce the blood pressure gradually as an abrupt fall can lead to cerebral ischaemia or infarctions (as in any accelerated hypertension). Calcium channel blockers may be added to ACE inhibitors.

Deterioration in renal function can be rapid, with gross pulmonary oedema; therefore patients with scleroderma renal crisis should be managed in hospitals with facilities for dialysis.

Question: 58 of 100

A 50-year-old female presents with acute chest pain and dyspnoea.

Examination reveals bilateral ankle oedema with 24 hour urine protein assessment showing 8g/d (<0.2).

Which is the most likely explanation for these findings?

(Please select 1 option)

○	Factor V Leiden
◉	Reduced antithrombin III activity ✓ Correct
○	Reduced concentration of von Willebrand's factor
○	Reduced factor VIII
○	Reduced fibrinogen concentration

This patient has developed nephrotic syndrome and appears to have had a thromboembolic event.

The suggestion is that she has had nephritic syndrome before developing the thromboembolism.

Deranged coagulation associated with nephrotic syndrome is a consequence of AT III deficiency, increased fibrinogen and increased factor VIIIc.

Next question | Tag Question | Remove question

Question: 59 of 100

You are called to the Emergency Department to assess a 21-year-old student who has presented with bloody diarrhoea.

The diarrhoea started two weeks previously and was associated with increasing nausea and malaise and mild swelling of the lower limbs. She was having difficulty passing urine. She had eaten steak from the local butcher at a friend's barbeque the day before developing diarrhoea.

On examination she was pale with evidence of petechiae over her legs. Her face appeared puffy. Blood pressure was 160/95 mmHg. She was apyrexial but had a tachycardia and crackles on inspiration at both lung bases. There was an old appendicectomy scar in the right iliac fossa.

Investigations showed:

Haemoglobin	8.5 g/dl	(11.5-16.5)
White cell count	13.2 x 10^9/l	(4-11)
Neutrophils	9.5 x 10^9/l	(1.5-7)
Platelets	35 x 10^9/l	(150-400)
PT	12 s	(11.5-15.5)
APTT	34 s	(30-40)
Fibrinogen	4 g/l	(1.8-5.4)
Serum sodium	139 mmol/l	(137-144)
Serum potassium	6.1 mmol/l	(3.5-4.9)
Serum urea	40 mmol/l	(2.5-7.5)
Serum creatinine	411 µmol/l	(60-110)

Platelets	35 x 10^9/l	(150-400)
PT	12 s	(11.5-15.5)
APTT	34 s	(30-40)
Fibrinogen	4 g/l	(1.8-5.4)
Serum sodium	139 mmol/l	(137-144)
Serum potassium	6.1 mmol/l	(3.5-4.9)
Serum urea	40 mmol/l	(2.5-7.5)
Serum creatinine	411 µmol/l	(60-110)
Serum albumin	27 g/l	(37-49)
Dipstick urine	Blood ++ Protein +	

What is the single most important next investigation to determine the diagnosis?

(Please select 1 option)

- ASO titres
- Renal tract ultrasound
- Stool culture
- Transthoracic echocardiogram
- Urine microscopy

passmedicine.com

○	Renal tract ultrasound
◉	Stool culture ✓ Correct
○	Transthoracic echocardiogram
○	Urine microscopy

This patient has haemolytic uraemic syndrome (HUS).

It typically presents with a triad of

- Acute renal failure (ARF)
- Microangiopathic haemolytic anaemia
- Thrombocytopaenia with normal clotting.

HUS is a complication of infection with verocytotoxin producing *Escherichia coli* usually of the serotype 0157:H7.

Toxins produced in the intestine enter the blood and bind to endothelial cells in target organs. Endothelial cell damage leads to platelet and fibrin deposition with resultant fragmentation of circulating red blood cells and microvascular occlusion.

The syndrome has also been reported after infections with coxsackie, echovirus and *Shigella*.

HUS is characterised by the sudden onset of haemolytic anaemia with fragmentation of red blood cells, thrombocytopaenia and acute renal failure after a prodromal illness of acute gastroenteritis often with bloody diarrhoea.

Clinical signs include increasing pallor, haematuria, oliguria and purpura. Jaundice is occasionally seen. Hypertension may be present.

Typical results show an anaemia, thrombocytopaenia, and often a neutrophilia. Blood film shows fragmented erythrocytes.

Urea and electrolytes are typical of acute renal failure. There is normal coagulation and fibrinogen.

Neurological complications include

- Stroke, seizure and coma occur in 25% of patients
- Rarely pancreatitis
- Pleural and pericardial effusions.

Approximately 5% of patients will develop end stage renal failure.

Long term renal sequelae range from proteinuria to chronic renal failure.

Therapy is supportive with

- correction of anaemia
- correction of uraemia by early dialysis
- strict fluid balance
- treatment of hypertension.

Major differential diagnosis is

1. Sepsis with DIC - presents with abnormalities of clotting parameters.
2. TTP - thrombotic thrombocytopaenic purpura presents with microangiopathic haemolytic anaemia, thrombocytopaenic purpura, neurologic abnormalities, fever, and renal disease.

Renal abnormalities tend to be more severe in HUS.

Although once considered variants of a single syndrome, recent evidence suggests that the pathogenesis of TTP and HUS is different. Patients with TTP lack a plasma protease that is responsible for the breakdown of von Willebrand factor (vWF) multimers and these accumulate in the plasma. The activity of this protease is normal in patients with HUS.

Until the test for vWF protease activity becomes available, differentiation between HUS and TTP is based on the presence of central

- correction of uraemia by early dialysis

Major differential diagnosis is

1. Sepsis with DIC - presents with abnormalities of clotting parameters.
2. TTP - thrombotic thrombocytopaenic purpura presents with microangiopathic haemolytic anaemia, thrombocytopaenic purpura, neurologic abnormalities, fever, and renal disease.

Renal abnormalities tend to be more severe in HUS.

Although once considered variants of a single syndrome, recent evidence suggests that the pathogenesis of TTP and HUS is different. Patients with TTP lack a plasma protease that is responsible for the breakdown of von Willebrand factor (vWF) multimers and these accumulate in the plasma. The activity of this protease is normal in patients with HUS.

Until the test for vWF protease activity becomes available, differentiation between HUS and TTP is based on the presence of central nervous system involvement in TTP and the more severe renal involvement in HUS.

In HUS 90% of patients are children and a history of prodromal diarrhoeal illness is more common.

The therapy of choice for TTP is plasma exchange with fresh frozen plasma.

Cr	382 mmol/l	(79-118)
Urine protein	++	
Blood	-	
White cells	-	

Which of the following is the most likely diagnosis?

(Please select 1 option)

○	Acute tubular necrosis
◉	Churg-Strauss syndrome ✕ Incorrect answer selected
○	Interstitial nephritis ← This is the correct answer
○	Membranous nephropathy
○	Pyelonephritis

The rapid onset of renal failure, coupled with a rash and eosinophilia is highly suspicious of a diagnosis of interstitial nephritis as a result of exposure to non-steroidal or amoxicillin.

Whilst eosinophilia is not usually seen in interstitial nephritis as a result of NSAIDs, it is seen in penicillin induced interstitial nephritis.

CT scanning and ultrasound are the main imaging modalities, with IVU being rarely used now. Renal biopsy is definitive in cases where the diagnosis is in doubt.

Resolution of renal failure usually begins after the causative agent is discontinued.

☆☆☆☆☆

A 16-year-old boy presents with periorbital and peripheral oedema which has developed over the past few weeks. He had a previous episode some two years earlier but this responded over the course of a few weeks to a course of prednisolone.

On examination he has a BP of 141/80 mmHg, with pulse of 68. His chest is clear but he has bilateral pitting oedema.

Investigations show

Haemoglobin	12.9 g/dl	(13.5-8)
White cell count	6.1 x 10^9/l	(4-10)
Platelets	209 x 10^9/l	(150-400)
Sodium	139 mmol/l	(134-143)
Potassium	4.8 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(60-120)
Albumin	24 g/l	(30-50)
Urine	Protein ++	

Which of the following represents the most appropriate management plan for him?

(Please select 1 option)

- Oral combination corticosteroids and cyclophosphamide
- Oral corticosteroids
- Oral cyclophosphamide
- Oral methotrexate
- Renal biopsy

Submit answer | Skip question | Tag Question | Remove question

Question: 60 of 100

A 60-year-old man presents with right foot drop, left foot and left hand numbness, fever, malaise, weight loss, polymyalgia and polyarthralgia of approximately one month duration.

On examination, he appears ill, with a temperature of 38.5°C and blood pressure of 180/100 mmHg.

Investigations reveal:

Haemoglobin	8.0 g/dL (13.0-18.0)
Erythrocyte sedimentation rate	100 mm/hr (0-20)
Serum creatinine	180 µmol/L (60-110)

- Urine analysis: Blood ++
- Urine microscopy: White cells and red cell casts

Which one of the following is the most likely diagnosis?

(Please select 1 option)

○	Antiphospholipid syndrome
○	Giant cell arteritis
○	Paraneoplastic syndrome
○	POEMS syndrome
○	Polyarteritis nodosa

Serum creatinine	180 µmol/L (60-110)

- Urine analysis: Blood ++
- Urine microscopy: White cells and red cell casts

Which one of the following is the most likely diagnosis?

(Please select 1 option)

○	Antiphospholipid syndrome
○	Giant cell arteritis
○	Paraneoplastic syndrome
○	POEMS syndrome
◉	Polyarteritis nodosa ✓ Correct

This patient has a mononeuritis multiplex, fever, hypertension, and nephritic renal involvement suggesting a diagnosis of PAN.

POEMS is a polyneuropathy, organomegaly, endocrinopathy and myeloma of which a few features are absent; and nephritic syndrome is not a feature.

Work Smart Session - MRCP Part 1

Question: 61 of 100

A 55-year-old man who has received haemodialysis for many years presents with deteriorating discomfort in both shoulders. Past medical history included bilateral carpal tunnel decompression.

His investigations reveal:

Haemoglobin	10 g/dl	(13.0-18.0)
ESR	30 mm/1st hr	(1-10)
C reactive protein	12 mg/l	(<10)
Urate	0.58 mmol/l	(<0.45)

What is the most likely diagnosis?

(Please select 1 option)

- ß2 microglobulin amyloidosis
- Gout
- Osteoarthritis
- Polymyalgia rheumatica
- Pseudogout

ESR	30 mm/1st hr	(1-10)
C reactive protein	12 mg/l	(<10)
Urate	0.58 mmol/l	(<0.45)

What is the most likely diagnosis?

(Please select 1 option)

- ◉ ß2 microglobulin amyloidosis ✓ Correct
- ○ Gout
- ○ Osteoarthritis
- ○ Polymyalgia rheumatica
- ○ Pseudogout

The features of shoulder pain associated with a past history of carpal tunnel syndrome in a patient receiving haemodialysis suggests a diagnosis of ß2 microglobulin amyloidosis.

Amyloid deposits composed of ß2 microglobulin as the major constituent protein are mainly localised in joints and periarticular bone and lead to destructive arthropathy which tends to develop five to ten years after the initiation of dialysis.

Death from amyloidosis of gut and heart may occur after 20 years of dialysis.

Work Smart Session - MRCP Part 1

Question: 62 of 100

A 23-year-old female presents at 16 weeks into her first pregnancy with a blood pressure of 144/96 mmHg. A 24 hour urine collection reveals a protein excretion of 0.7 g/d (<0.2)

What is the most likely explanation for these findings?

(Please select 1 option)

- Essential hypertension
- Gestational hypertension
- Normal changes of pregnancy
- Pre-eclampsia
- Secondary hypertension

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Question: 62 of 100

A 23-year-old female presents at 16 weeks into her first pregnancy with a blood pressure of 144/96 mmHg. A 24 hour urine collection reveals a protein excretion of 0.7 g/d (<0.2)

What is the most likely explanation for these findings?

(Please select 1 option)

◉	Essential hypertension ✗ Incorrect answer selected
○	Gestational hypertension
○	Normal changes of pregnancy
○	Pre-eclampsia
○	Secondary hypertension ← This is the correct answer

This pregnant woman has hypertension and proteinuria (as defined by a blood pressure above 140/90 mmHg and proteinuria above 0.3 g/d). It would not be regarded as normal to have this high a blood pressure or protein content of urine.

Pre-eclampsia is a disease occurring in the second half of pregnancy (after 20 weeks gestation), and conventionally, characterised by pregnancy-induced hypertension with proteinuria and often with oedema.

Gestational hypertension is defined as blood pressure elevation detected for the first time after midpregnancy, without proteinuria.

Essential hypertension is unlikely in this female as there is a suggestion of renal disease which makes secondary hypertension the likely option.

Remove Tag | Remove question

Question: 63 of 100

A 45-year-old lady presents with fatigue and lethargy, and has established end stage renal failure. She has been on haemodialysis for the past three years and receives dialysis for three hours three times a week at a regional haemodialysis centre.

At one of her regular visits for haemodialysis she is found to have the following observations and investigations.

Blood pressure	170/95	
Serum K^+	5.7 mmol/l	(3.5-4.9)
Serum corrected calcium	2.0 mmol/l	(2.2-2.6)
Hb	9.0 g/dl	(11.5-16.5)
Creatinine	1300 mol/l	(60-110)

Post-dialysis her blood pressure is recorded as 160/95 mmHg.

Which of the following is the best option for management of this lady's symptoms?

(Please select 1 option)

- ○ Increase dialysis hours
- ○ Treat anaemia with erythropoietin
- ○ Treat hyperkalaemia
- ○ Treat hypocalcaemia
- ○ Treat hypertension with ramipril

Which of the following is the best option for management of this lady's symptoms?

(Please select 1 option)

○	Increase dialysis hours
◉	Treat anaemia with erythropoietin ✓ Correct
○	Treat hyperkalaemia
○	Treat hypocalcaemia
○	Treat hypertension with ramipril

This person's main complaint is of fatigue. Treating her with erythropoietin would therefore be the most appropriate therapy particularly with her anaemia.

Increasing dialysis is unlikely to be acceptable to most patients and renal units though this is an option some patients would choose, especially those on 'home haemodialysis'.

Vascular disease is an important cause of death in dialysis patients and this lady may very well need additional treatment of blood pressure.

◉	Membranous nephropathy ✓ Correct
○	Minimal change nephropathy

This young woman has thromboembolic disease, the nephrotic syndrome with positive anti-ds DNA antibodies suggests a diagnosis of systemic lupus erythematosus.

Nephrotic syndrome in the absence of hypertension, active urinary sediment, or significant hypocomplementaemia suggests membranous nephropathy.

The thromboembolic disease may arise due to nephrotic syndrome per se or from an associated antiphospholipid syndrome.

Work Smart Session - MRCP Part 1

Question: 65 of 100

A 68-year-old male is referred by his general practitioner with deteriorating hypertension and renal function.

Investigations show:

Serum creatinine	250 mol/L (60-110)
Urinalysis	+ protein

Renal ultrasound scan:

- left kidney 9 cm long
- right kidney 7 cm, no obstruction (10-12 cm)

Which of the following would be the most appropriate investigation for this patient?

(Please select 1 option)

○	Intravenous renography
○	Isotope renography
○	MR angiography
○	Renal biopsy
○	Retrograde pyelography

Renal ultrasound scan:

- left kidney 9 cm long
- right kidney 7 cm, no obstruction (10-12 cm)

Which of the following would be the most appropriate investigation for this patient?

(Please select 1 option)

○	Intravenous renography
○	Isotope renography
◉	MR angiography ✓ Correct
○	Renal biopsy
○	Retrograde pyelography

The diagnosis is likely to be atherosclerotic renal artery stenosis (RAS) as suggested by the asymmetric reduction in renal size, with mild proteinuria quite common in the condition.

Investigations include captopril renography, magnetic resonance (MR) angiography which is virtually as good as renal arteriography.

None of the other investigations are appropriate for RAS.

Time taken: 4 hrs 46 mins 53 secs

Work Smart Session - MRCP Part 1

Question: 66 of 100

A 72-year-old male presented to his GP with depression after the death of his wife.

His notes also reveal that he has a two year history of urinary hesitancy and poor stream. His GP prescribed him some medication and the following day he developed acute urinary retention.

Which of the following drugs is most likely to have precipitated the urinary retention?

(Please select 1 option)

- Amitriptyline
- Diazepam
- Fluoxetine
- Venlafaxine
- Zopiclone

Submit answer | Skip question | Tag Question | Remove question

and the following day he developed acute urinary retention.

Which of the following drugs is most likely to have precipitated the urinary retention?

(Please select 1 option)

◉	Amitriptyline ✓ Correct
○	Diazepam
○	Fluoxetine
○	Venlafaxine
○	Zopiclone

Amitriptyline has anticholinergic effects, being associated with tachycardia, dry mouth and urinary retention.

These features are not typical of selective serotonin reuptake inhibitors (SSRIs) such as venlafaxine and fluoxetine, with urinary retention and dry mouth rarely reported.

Diazepam, a benzodiazepine does not have anticholinergic effects.

Zopiclone is a benzodiazepine-like agent whose side effects include drowsiness.

Work Smart Session - MRCP Part 1

Question: 67 of 100

Which of the following is a known risk factor for the development of chronic rejection of kidney transplantation?

(Please select 1 option)

○	Age
○	Anti-smooth muscle antibodies
○	Presence of anti-HLA antibodies
○	Smoking
○	Toxoplasma infection

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Presence of anti-HLA antibodies ← This is the correct answer
◉	Smoking ✕ Incorrect answer selected
○	Toxoplasma infection

Chronic rejection is characterised by fibrosis of normal organ structures.

The pathogenesis of chronic rejection is not clear - some prefer the term "chronic allograft dysfunction" since both immunological (antigen-dependent and antigen-independent) and non-immunological factors have been identified.

Cell-mediated and humoral immune mechanisms have been implicated in this form of graft rejection.

It has also been suggested that rejection is a response to chronic ischaemia caused by injury to endothelial cells.

Proliferation of intimal smooth muscle is observed leading to vascular occlusion.

The fact that chronic rejection is rare in transplants between human leukocyte antigen (HLA)-identical siblings suggests that HLA-antigen dependent immunological factors are important.

Risk factors include:

- Number of previous acute rejection episodes
- Presence of anti-HLA antibodies
- Anti-endothelial antibodies
- Cytomegalovirus (CMV) infection
- Dyslipidaemia
- Hypertension
- Functional mass of the donor kidney and
- Delayed graft function (a clinical manifestation of ischaemia/reperfusion injury).

Time taken: 4 hrs 51 mins 43 secs

Work Smart Session - MRCP Part 1

Question: 68 of 100

Which one of the following cytokines is strongly implicated in renal scarring?

(Please select 1 option)

○	Interferon alpha
○	Interleukin-1
○	Granulocyte colony stimulating factor
○	Transforming growth factor-beta ← This is the correct answer
◉	Tumour necrosis factor alpha ✕ Incorrect answer selected

TGF-beta is a potent recruiter for fibroblasts which are implicated in renal scarring.

IFN-alpha is implicated more in lymphocyte response and IL-1/TNF-alpha in the acute phase response.

G-CSF is a stimulant of granulocyte cell line maturation.

Work Smart Session - MRCP Part 1

Question: 69 of 100

A 45-year-old man on regular haemodialysis complained of weakness and exertional fatigue. On examination, his blood pressure was 170/105 mmHg (pre-dialysis) and 160/95 mmHg (post-dialysis).

Investigations pre-dialysis revealed:

Haemoglobin	9.0 g/dl	(13.0-18.0)
Serum potassium	6.9 mmol/l	(3.5-4.9)
Serum creatinine	1250 µmol/l	(60-110)
Serum corrected calcium	2.1 mmol/l	(2.2-2.6)

Which intervention is most likely to improve his symptoms?

(Please select 1 option)

- ○ Correct hypocalcaemia with alfacalcidol
- ○ Improve blood pressure control with ramipril
- ○ Increase haemoglobin with epoetin
- ○ Increase the length of each dialysis session
- ○ Lower the potassium in the dialysate

Submit answer | Skip question | Tag Question | Remove question

Serum corrected calcium	2.1 mmol/l	(2.2-2.6)

Which intervention is most likely to improve his symptoms?

(Please select 1 option)

○	Correct hypocalcaemia with alfacalcidol
○	Improve blood pressure control with ramipril
◉	Increase haemoglobin with epoetin ✓ Correct
○	Increase the length of each dialysis session
○	Lower the potassium in the dialysate

This is a tough question with many possible answers. But and importantly, this question asks: how to improve his symptoms? Changing the question around, such as how to improve blood pressure or how to improve prognosis alters the answer.

There are several deficiencies in the management of this patient with end stage renal failure. The symptoms described are more in keeping with his anaemia.

A mild hypocalcaemia and hyperkalaemia would not give rise to his symptoms. This also applies to his uncontrolled hypertension. His pre-dialysis creatinine implies he is under-dialysed but would not give rise to exertional fatigue.

Bearing in mind all the above the question specifically asks what intervention would improve his symptoms. In which case one would have to elect EPO irrespective of blood pressure, calcium, etc.

Next question

Rate this question

White cell count	6.1 x 10^9/l	(4-10)
Platelets	209 x 10^9/l	(150-400)
Sodium	139 mmol/l	(134-143)
Potassium	4.8 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(60-120)
Albumin	24 g/l	(30-50)
Urine	Protein ++	

Which of the following represents the most appropriate management plan for him?

(Please select 1 option)

- ○ Oral combination corticosteroids and cyclophosphamide
- ◉ Oral corticosteroids ✓ Correct
- ○ Oral cyclophosphamide
- ○ Oral methotrexate
- ○ Renal biopsy

The age of this patient and his previous response to corticosteroids is suggestive of an underlying diagnosis of minimal change nephropathy. As such, a further course of corticosteroids is the treatment of choice.

Given the inherent but low risks associated with renal biopsy, it is usually only attempted when three or more episodes of oedema have occurred.

Very few patients with minimal change disease actually progress to end stage renal disease, and only around 10% of children with the disease suffer from hypertension.

Work Smart Session - MRCP Part 1

Question: 7 of 100

A 57-year-old woman who has been receiving haemodialysis for the past five years is found dead in bed by her husband. She had a long history of type 1 diabetes for over 20 years and in her later years suffered from neuropathy and retinopathy as well as chronic renal failure. Most recently she was under investigation for angina.

Which of the following is the most likely cause of death in this patient?

(Please select 1 option)

- Hyperkalaemia
- Hypoglycaemia
- Myocardial infarction
- Pulmonary embolus
- Stroke

Submit answer | Skip question | Tag Question | Remove question

Question: 70 of 100

A 45-year-old man had recurrent nephrolithiasis.

Renal function tests and serum calcium measurements were normal.

A 24 hour urine collection revealed:

Volume	3L
Calcium	15 mmol/24 hours (2.5-7.5)
Oxalate	200 mmol/24 hours (90-450)
Uric acid	3 mmol/24 hours (1.48-4.45)
Citrate	2mmol/24hours (0.3-3.4)

What is the most useful therapy to reduce stone formation?

(Please select 1 option)

- ○ Allopurinol
- ○ Dietary calcium restriction
- ○ Penicillamine
- ○ Potassium citrate
- ○ Thiazide diuretic

Uric acid	3 mmol/24 hours (1.48-4.43)
Citrate	2mmol/24hours (0.3-3.4)

What is the most useful therapy to reduce stone formation?

(Please select 1 option)

○	Allopurinol
○	Dietary calcium restriction
○	Penicillamine
○	Potassium citrate
◉	Thiazide diuretic ✓ Correct

This patient has hypercalciuria and thiazide diuretics can decrease urinary excretion of calcium and possibly oxalate.

Dietary calcium restriction will not limit calciuria, given the large amount of calcium that can be mobilised from bone.

The lack of hyperuricosuria and hypocitratraturia excludes the other treatments offered.

Work Smart Session - MRCP Part 1

Question: 71 of 100

A 30-year-old woman presented with hypertension (160/110 mmHg), elevated titres of antibodies to double-stranded DNA, and proteinuria (1g per 24 hours).

A renal biopsy demonstrated WHO class II lupus nephritis (mesangial disease).

What is the most appropriate single treatment for this patient?

(Please select 1 option)

- Antihypertensive medication
- High-dose corticosteroids
- Intravenous cyclophosphamide
- Oral cyclophosphamide
- Plasma exchange

Submit answer | Skip question | Tag Question | Remove question

- Shop
- Help

A renal biopsy demonstrated WHO class II lupus nephritis (mesangial disease).

What is the most appropriate single treatment for this patient?

(Please select 1 option)

○	Antihypertensive medication ← This is the correct answer
◉	High-dose corticosteroids ✕ Incorrect answer selected
○	Intravenous cyclophosphamide
○	Oral cyclophosphamide
○	Plasma exchange

There is good evidence that immunosuppression could alter outcome in the presence of proliferative glomerulonephritis but not in mesangial or membranous glomerulonephritis.

Therefore the best line of treatment would be a conservative approach to address risk factors for progression of renal impairment such as uncontrolled hypertension.

There is no good evidence to support plasma exchange as an effective treatment modality in lupus nephritis.

Time taken: 4 hrs 55 mins 55 secs

Work Smart Session - MRCP Part 1

Question: 72 of 100

A 60-year-old man wishes to act as a kidney donor to his 37-year-old wife.

She has end stage renal failure from polycystic kidney disease and is maintained on peritoneal dialysis.

The couple have two teenage daughters, neither of whom have renal cysts on recent ultrasound scans.

Which one of the following statements is correct?

(Please select 1 option)

○	Living related donation from one of the daughters would be preferable to donation from the husband
○	Living unrelated donation is not recommended in cases of inherited renal disease
○	The age difference between husband and wife is a relative contraindication to transplantation
○	The husband should not be accepted for kidney donation until all siblings have been considered
○	The results of living unrelated kidney donation are sufficiently poor that organ donation should not proceed

Submit answer | Skip question | Tag Question | Remove question

- Help

The couple have two teenage daughters, neither of whom have renal cysts on recent ultrasound scans.

Which one of the following statements is correct?

(Please select 1 option)

○	Living related donation from one of the daughters would be preferable to donation from the husband
○	Living unrelated donation is not recommended in cases of inherited renal disease
◉	The age difference between husband and wife is a relative contraindication to transplantation ✕ Incorrect answer selected
○	The husband should not be accepted for kidney donation until all siblings have been considered ← This is the correct answer
○	The results of living unrelated kidney donation are sufficiently poor that organ donation should not proceed

Providing there is a sibling who is proven not to have polycystic kidney disease, living related donation should be considered as this would ensure a better match and better graft survival.

As teenagers polycystic kidney disease may not be manifest ultrasonographically in her daughters.

Living unrelated kidney donation does not produce bad results. In patients with polycystic kidney disease, or for other inherited diseases, a graft from an unrelated donor would not necessarily succumb to the same disease process.

Where there is a shortage of donors the age difference certainly would not be considered a relative contraindication to kidney donation.

Time taken: 4 hrs 58 mins 2 secs

Work Smart Session - MRCP Part 1

Question: 73 of 100

A 25-year-old man developed bilateral loin pain and frank haematuria.

His symptoms had started 24 hours after developing a sore throat. His blood pressure was 138/88 mmHg. Urinalysis was positive for blood (4+) and protein (2+).

What is the most likely diagnosis?

(Please select 1 option)

○	IgA nephropathy
○	Microscopic polyangiitis
○	Nephrolithiasis
○	Post-streptococcal glomerulonephritis
○	Septicaemia

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 25-year-old man developed bilateral loin pain and frank haematuria.

His symptoms had started 24 hours after developing a sore throat. His blood pressure was 138/88 mmHg. Urinalysis was positive for blood (4+) and protein (2+).

What is the most likely diagnosis?

(Please select 1 option)

◉	IgA nephropathy ✓ Correct
○	Microscopic polyangiitis
○	Nephrolithiasis
○	Post-streptococcal glomerulonephritis
○	Septicaemia

The acute onset of the disease is suggestive of IgA nephropathy which characteristically occurs in young males in their 20s and 30s.

Haematuria occurs within 12-24 hours of pharyngitis, accompanied also by loin pain, muscle pain and fever. Prognosis is usually good especially in children. In adults, between 25-50% may develop end-stage renal failure. No specific treatment available.

Classically, the patient has streptococcal infection one to three weeks before the onset of acute nephritic syndrome (post-strep GN).

There is a long prodromal systemic illness lasting months or years in microscopic polyangiitis which differs from Wegener's granulomatosis in its absence of respiratory tract granulomatous inflammation.

Time taken: 4 hrs 58 mins 54 secs

Work Smart Session - MRCP Part 1

Question: 74 of 100

A 49-year-old woman has been an in-patient for the past 10 days for treatment of a bronchopneumonia. She has developed the onset of chills, fever, and skin rash over the past two days.

A peripheral blood film reveals eosinophilia. On urinalysis she has ++ proteinuria. There is no past history of renal disease. Her haemoglobin A_{1c} is normal.

These findings would most strongly suggest which of the following diagnoses?

(Please select 1 option)

○	Acute serum sickness
○	Acute tubular necrosis
○	Drug-induced interstitial nephritis
○	IgA nephropathy
◉	Post-streptococcal glomerulonephritis (GN)

Submit answer | Skip question | Tag Question | Remove question

onset of chills, fever, and skin rash over the past two days.

A peripheral blood film reveals eosinophilia. On urinalysis she has ++ proteinuria. There is no past history of renal disease. Her haemoglobin A_{1c} is normal.

These findings would most strongly suggest which of the following diagnoses?

(Please select 1 option)

○	Acute serum sickness
○	Acute tubular necrosis
○	Drug-induced interstitial nephritis ← This is the correct answer
○	IgA nephropathy
◉	Post-streptococcal glomerulonephritis (GN) ✕ Incorrect answer selected

The findings are typical of a drug-induced acute interstitial nephritis.

Post-streptoccocal GN appears weeks after the acute infection.

Berger's disease (IgA nephropathy) is characterised by haematuria and often follows a 'flu-like' illness.

Eosinophilia is not typical for serum sickness.

Question: 75 of 100

A 60-year-old man was diagnosed last year with adenocarcinoma of the lung and a 4 cm mass lesion was treated with a right lower lobectomy.

He now has an abdominal CT scan that reveals scattered hepatic mass lesions and hilar lymphadenopathy. For several weeks, he has had increasing malaise.

His results show

Urinalysis	Protein +++
24 hour urine protein	2.7 g/24hr
Serum urea	30 mmol/L (2.5-7.5)
Serum creatinine	450 µmol/L (60-110)

A renal biopsy shows focal deposition of IgG and C3 with a granular pattern.

What is the most likely diagnosis?

(Please select 1 option)

- ○ Goodpasture's syndrome
- ○ Membranous glomerulonephritis
- ○ Minimal change glomerulonephritis
- ○ Nodular glomerulosclerosis
- ○ Rapidly progressive glomerulonephritis

had increasing malaise.

His results show

Urinalysis	Protein +++
24 hour urine protein	2.7 g/24hr
Serum urea	30 mmol/L (2.5-7.5)
Serum creatinine	450 µmol/L (60-110)

A renal biopsy shows focal deposition of IgG and C3 with a granular pattern.

What is the most likely diagnosis?

(Please select 1 option)

○	Goodpasture's syndrome
○	Membranous glomerulonephritis ← This is the correct answer
○	Minimal change glomerulonephritis
○	Nodular glomerulosclerosis
◉	Rapidly progressive glomerulonephritis ✕ Incorrect answer selected

Most cases of membranous GN are idiopathic, but in some patients there is a history of an infection or a malignancy (usually lung) with antigenemia.

Question: 76 of 100

A 15-year-old girl was seen by her family physician because of increasing lethargy. She had a recent history of the "flu".

Biochemistry tests show that she has renal impairement.

Serum sodium	140 mmol/L (137-144)
Serum potassium	4.2 mmol/L (3.5-4.9)
Serum urea	28 mmol/L (2.5-7.5)
Serum creatinine	280 µmol/L (60-110)

Her condition does not improve after several weeks on corticosteroid therapy, so a renal biopsy is performed. The biopsy demonstrates the presence of segmental sclerosis of 3 of 10 glomeruli identified in the biopsy specimen.

Immunofluorescence studies and electron microscopy do not reveal evidence for immune deposits.

What is the most appropriate advice to give regarding her condition?

(Please select 1 option)

- She has an underlying malignancy
- She may require a renal transplant in 10 years
- She will improve if she loses weight
- She will likely develop a restrictive lung disease
- She will probably improve with additional corticosteroid therapy

Serum potassium	4.2 mmol/L (3.5-4.9)
Serum urea	28 mmol/L (2.5-7.5)
Serum creatinine	280 µmol/L (60-110)

Her condition does not improve after several weeks on corticosteroid therapy, so a renal biopsy is performed. The biopsy demonstrates the presence of segmental sclerosis of 3 of 10 glomeruli identified in the biopsy specimen.

Immunofluorescence studies and electron microscopy do not reveal evidence for immune deposits.

What is the most appropriate advice to give regarding her condition?

(Please select 1 option)

○	She has an underlying malignancy
◉	She may require a renal transplant in 10 years ✓ Correct
○	She will improve if she loses weight
○	She will likely develop a restrictive lung disease
○	She will probably improve with additional corticosteroid therapy

The findings point to focal segmental glomerulosclerosis (FSGS) which leads to chronic renal failure in half of cases.

The lack of resolution with corticosteroid therapy and the progression to chronic renal failure is what sets FSGS apart from minimal change disease.

Work Smart Session - MRCP Part 1

Question: 77 of 100

A 66-year-old man has developed chronic renal failure with a serum urea of 60 mmol/l (2.5-7.5) and creatinine of 650 mol/l (60-110).

Auscultation of the chest reveals a friction rub over the cardiac apex.

Which of the following types of pericarditis is he likely to have?

(Please select 1 option)

- Constrictive
- Fibrinous
- Haemorrhagic
- Purulent
- Serous

Submit answer | Skip question | Tag Question | Remove question

Time taken: 5 hrs 6 mins 57 secs

Work Smart Session - MRCP Part 1

Question: 77 of 100

A 66-year-old man has developed chronic renal failure with a serum urea of 60 mmol/l (2.5-7.5) and creatinine of 650 mol/l (60-110).

Auscultation of the chest reveals a friction rub over the cardiac apex.

Which of the following types of pericarditis is he likely to have?

(Please select 1 option)

○	Constrictive
◉	Fibrinous ✓ Correct
○	Haemorrhagic
○	Purulent
○	Serous

The uraemia leads to exudation of fibrin onto the epicardial and pericardial surfaces.

Haemorrhagic pericarditis is more typical of tuberculosis or metastatic tumour.

Serous pericarditis is more typical of collagen vascular diseases.

Work Smart Session - MRCP Part 1

Question: 78 of 100

Which one of the following statements regarding renal function is correct?

(Please select 1 option)

○	A ten minute period of hyperventilation will normally be expected to lead to an increased rate of bicarbonate excretion in urine
○	Sodium reabsorption in the tubules is mainly controlled by aldosterone
○	The daily solute excretion will lie between 75 and 300 mosmol
○	The permeability of the proximal nephron to water increases in the presence of vasopressin
○	The rate of ammonium excretion in urine is inversely related to the rate of urinary hydrogen ion excretion

(Please select 1 option)

○	A ten minute period of hyperventilation will normally be expected to lead to an increased rate of bicarbonate excretion in urine ← This is the correct answer
○	Sodium reabsorption in the tubules is mainly controlled by aldosterone
◉	The daily solute excretion will lie between 75 and 300 mosmol ✕ Incorrect answer selected
○	The permeability of the proximal nephron to water increases in the presence of vasopressin
○	The rate of ammonium excretion in urine is inversely related to the rate of urinary hydrogen ion excretion

Arginine vasopressin (AVP) acts on the collecting ducts increasing permeability to water.

The total solute excretion is approximately 700 mosmol/d.

Sodium reabsorption is mostly through active transport in the loop of Henle with only a modest reabsorption facilitated by aldosterone.

A ten minute period of hyperventilation would cause a respiratory alkalosis leading to an increased secretion of bicarbonate and retention of hydrogen ions.

The rate of ammonium excretion is proportional to the rate of hydrogen ion excretion.

Time taken: 5 hrs 10 mins 18 secs

Work Smart Session - MRCP Part 1

Question: 79 of 100

Which one of the following statements is correct?

(Please select 1 option)

○	Adult polycystic renal disease is inherited as an autosomal recessive trait
○	Alport's syndrome affects females more severely than males
◉	Medullary sponge kidney is typically not inherited but is a congenital condition. ✓ Correct
○	Nephrogenic diabetes insipidus (DI) is inherited as an autosomal dominant trait
○	Reflux nephropathy is inherited as an autosomal recessive trait

Polycystic kidney disease (PKD) is usually autosomal dominant although the infantile form is autosomal recessive.

Nephrogenic DI is usually X-linked.

Features of Alport's syndrome (hereditary nephritis, haematuria, progressive renal failure and high-frequency nerve deafness) are usually more marked in in males.

Neither reflux nephropathy nor medullary sponge kidneys are hereditary conditions.

A 57-year-old woman who has been receiving haemodialysis for the past five years is found dead in bed by her husband. She had a long history of type 1 diabetes for over 20 years and in her later years suffered from neuropathy and retinopathy as well as chronic renal failure. Most recently she was under investigation for angina.

Which of the following is the most likely cause of death in this patient?

(Please select 1 option)

○	Hyperkalaemia
○	Hypoglycaemia
◉	Myocardial infarction ✓ Correct
○	Pulmonary embolus
○	Stroke

Patients who undergo long term haemodialysis suffer from increasing arterial calcification, which is associated with both increased risk of myocardial infarction and stroke, but the greatest absolute increase is in MI rates.

Interestingly, trials of high dose statins have proved disappointing in the dialysis population, suggesting that calcification drives much of the increased risk.

Whilst both hypoglycaemia and hyperkalaemia are alternative possibilities as causes of death, myocardial infarction is more likely than both to have been responsible.

A 34-year-old man presents with worsening shortness of breath, wheeze, lethargy and nausea. He has a history of asthma which has been managed by one of your partners with salbutamol and a twice daily combination of a long acting beta-2 agonist and an inhaled steroid inhaler.

On examination his BP is 150/92 mmHg, his pulse is 80 and regular. He has extensive wheeze throughout both lung fields.

Investigations show

Haemoglobin	11.8 g/dl	(13.5-18)
White cell count	10.1 x 10^9/l (Eosinophils 30%)	(4-10)
Platelets	190 x 10^9/l	(150-400)
Sodium	140 mmol/l	(134-143)
Potassium	4.9 mmol/l	(3.5-5)
Creatinine	189 µmol/l	(60-120)
ESR	62	(<10)
Urine	Blood++ Protein ++	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- Alport's syndrome
- Churg-Strauss syndrome
- IgA nephropathy

Work Smart Session - MRCP Part 1

Question: 80 of 100

Which of the following statements regarding idiopathic membranous nephropathy is correct?

(Please select 1 option)

○	Immune complex deposits are typically seen in the glomerular mesangium.
○	It characteristically presents in the first decade of life.
○	Males are twice as commonly affected as females.
○	Progression to end-stage renal failure is rapid.
○	The nephritic syndrome is a characteristic presentation.

Work Smart Session - MRCP Part 1

Question: 80 of 100

Which of the following statements regarding idiopathic membranous nephropathy is correct?

(Please select 1 option)

○	Immune complex deposits are typically seen in the glomerular mesangium.
○	It characteristically presents in the first decade of life.
◉	Males are twice as commonly affected as females. ✓ Correct
○	Progression to end-stage renal failure is rapid.
○	The nephritic syndrome is a characteristic presentation.

Membranous nephropathy is characterised by thickened basement membranes and monotonous granular deposits of IgG and C3 distributed in the epimembranous space of virtually all glomerular capillaries.

The mesangium may be involved at a later stage of the disease and is more typical of secondary disease.

It is typically seen in the over 40 age group with a male predominance of 2 to 1 and is associated with a variable prognosis with 25% developing endstage renal failure (ESRF) over 10 years and 25% going into remission. There is a higher rate of remission for the idiopathic form.

The majority of patients manifest with a pure nephrotic syndrome.

A nephritic presentation is rare.

Work Smart Session - MRCP Part 1

Question: 81 of 100

Which of the following is a feature of cystinuria?

(Please select 1 option)

- Accumulation of cystine in the kidney
- A useful response to acidification of urine
- Autosomal dominant inheritance
- Excessive urinary arginine excretion
- Radiolucent urinary calculi

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which of the following is a feature of cystinuria?

(Please select 1 option)

◉	Accumulation of cystine in the kidney ✗ Incorrect answer selected
○	A useful response to acidification of urine
○	Autosomal dominant inheritance
○	Excessive urinary arginine excretion ← This is the correct answer
○	Radiolucent urinary calculi

Cystinuria is the commonest inborn error of amino acid transport.

Amino acids excreted in urine are cystine, ornithine, arginine and lysine (mnemonic - COAL).

The renal stones are radio-opaque due to the presence of sulphur.

It is inherited as an autosomal recessive condition.

Management includes alkalinisation along with high fluid intake (>4 L/day); d-penicillamine may also be used.

It is cystinosis that leads to accumulation of cystine in the kidney.

Work Smart Session - MRCP Part 1

Question: 82 of 100

In chronic untreated renal failure which of the following findings is characteristic?

(Please select 1 option)

○	Hypercalcaemia
○	Hypercalcinuria
○	Hyperosmolar dehydration
○	Hypokalaemia
○	Metabolic alkalosis

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Hypercalcaemia
○	Hypercalcinuria ← This is the correct answer
○	Hyperosmolar dehydration
○	Hypokalaemia
◉	Metabolic alkalosis ✕ Incorrect answer selected

Major pathophysiological abnormalities of chronic renal failure:

- Accumulation of nitrogenous waste products
- Acidosis: bicarbonate wasting, decreased ammonia secretion, decreased acid excretion
- Sodium wasting: solute diuresis, tubular damage
- Sodium retention: nephrotic syndrome, CCF, anuria, excess sodium intake
- Urinary concentrating defect: nephron loss, solute diuresis
- Hyperkalaemia: decreased glomerular filtration rate (GFR), acidosis, hyperaldosteronism
- Renal osteodystrophy: decreased intestinal calcium absorption, impaired 12-dihydroxy vitamin D production, secondary hyperparathyroidism
- Growth retardation: protein calorie deficiency, renal osteodystrophy, acidosis, anaemia
- Anaemia: decreased erythropoeitin production, low grade haemolysis, inadequate intake
- Bleeding tendency: thrombocytopenia, decreased platelet function
- Infection: defective granulocyte function
- Neurology: uraemia, aluminium toxicity results in fatigue, poor concentration, headache, memory loss, slurred speech, muscle weakness and cramps, seizures and coma
- GI ulceration: gastric acid hypersecretion

Major pathophysiological abnormalities of chronic renal failure:

Work Smart Session - MRCP Part 1

Question: 83 of 100

Which of the following is characteristic of Bartter's syndrome?

(Please select 1 option)

○	Diarrhoea
○	Hyperkalaemia
○	Metabolic acidosis
○	Secondary hyperaldosteronism
○	Reduced renal concentrating ability

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

○	Diarrhoea
○	Hyperkalaemia
○	Metabolic acidosis
◉	Secondary hyperaldosteronism ✓ Correct
○	Reduced renal concentrating ability

Bartter's syndrome is a rare form of renal potassium wasting characterised by hypokalaemia, normotension, and elevated renin and aldosterone levels.

It is occasionally autosomal recessive.

There is hyperplasia of the juxtaglomerular apparatus in most cases.

It is postulated that the primary defect is in chloride reabsorption in the ascending limb, resulting in sodium chloride excessively presented to the distal tubule, with sodium reabsorption in exchange for potassium, resulting in urinary sodium wasting.

There is secondary stimulation of prostaglandin synthesis, which activates the renin angiotensin aldosterone system which exacerbates the renal potassium wasting.

Younger children typically present with

- growth failure
- muscle weakness
- constipation
- polyuria
- dehydration

There is secondary stimulation of prostaglandin synthesis, which activates the renin angiotensin aldosterone system which exacerbates the renal potassium wasting.

Younger children typically present with

- growth failure
- muscle weakness
- constipation
- polyuria
- dehydration.

Older children typically present with

The potassium is <2.5 mmol/l, there is metabolic alkalosis, and hyperammonaemia with hyperaldosteronism.

There are high levels of urinary potassium and chloride.

The high urinary chloride level is helpful in distinguishing it from similar presentations which have low urinary chloride levels, such as

- liquorice, laxative, or diuretic use
- persistent vomiting or diarrhoea
- pyelonephritis
- diabetes insipidus.

Oral potassium and indomethacin may be used.

Question: 84 of 100

Which of the following is associated with hyperuricaemia?

(Please select 1 option)

○	Can be reduced with low dose aspirin therapy
○	Can be treated with uricosuric drugs even in renal failure
○	In primary gout is inherited in an autosomal dominant manner
○	Is usually due to an excess purine consumption
○	Occurs in association with acute lymphoblastic leukaemia

Submit answer | Skip question | Tag Question | Remove question

Which of the following is associated with hyperuricaemia?

(Please select 1 option)

○	Can be reduced with low dose aspirin therapy
○	Can be treated with uricosuric drugs even in renal failure
○	In primary gout is inherited in an autosomal dominant manner
○	Is usually due to an excess purine consumption
◉	Occurs in association with acute lymphoblastic leukaemia ✓ Correct

Hyperuricaemia may be due to increased purine intake, urate production or reduced urate clearance, and is most commonly due to the latter.

Therefore it can occur in association with enhanced cell destruction, particularly leukaemias.

Primary gout has no obvious mode of inheritance, but familial juvenile gouty nephropathy is an autosomal dominantly inherited disorder.

Low dose aspirin may exacerbate gout but high dose aspirin is uricosuric.

Many of the uricosuric drugs may be detrimental in renal failure and may not be effective.

Work Smart Session - MRCP Part 1

Question: 85 of 100

Which of the following is true concerning a 68-year-old male with type 2 diabetes diagnosed with type IV renal tubal acidosis (RTA)?

(Please select 1 option)

○	Aminoaciduria would be expected
○	Fludrocortisone treatment is effective
○	Increased glomerular filtration rate (GFR) is expected
○	Increased urinary bicarbonate would be expected
○	Normal renal handling of K^+ and H^+

Submit answer | Skip question | Tag Question | Remove question

Time taken: 5 hrs 17 mins 53 secs

Work Smart Session - MRCP Part 1

Question: 85 of 100

Which of the following is true concerning a 68-year-old male with type 2 diabetes diagnosed with type IV renal tubal acidosis (RTA)?

(Please select 1 option)

◉	Aminoaciduria would be expected ✕ Incorrect answer selected
○	Fludrocortisone treatment is effective ← This is the correct answer
○	Increased glomerular filtration rate (GFR) is expected
○	Increased urinary bicarbonate would be expected
○	Normal renal handling of K^+ and H^+

H^+ secretion, sodium reabsorption and ammonia production diminishes.

RTA 4 is, in effect, hyporeninaemic hypoaldosteronism or failure of aldosterone action, and thus helped treated with mineralocorticoids. It is usually seen in chronic renal disease and hence low GFR and particularly.

Aminoaciduria and increased urine bicarbonate are features of RTA types 1 and 2.

Work Smart Session - MRCP Part 1

Question: 86 of 100

Which of the following concerning the pH of urine is correct?

(Please select 1 option)

○	a. Is a useful indicator of the acid/base balance of the blood
◉	b. Rises on a vegetarian diet ✓ Correct
○	c. Is determined by the concentration of ammonium
○	d. Is lower than 5.5 in renal tubular acidosis (RTA)
○	e. Would be above 7.0 after prolonged and severe vomiting

c. Excretion of ammonium occurs when an acid urine is produced but the pH of urine is of course determined by the concentration of H+ ions.

d. Unable to lower the pH to less than 5.5 in RTA.

e. This would be expected in an attempt to compensate for the loss of acid; however when there is extracellular fluid depletion the retention of sodium takes priority.

Instead of bicarbonate being excreted it is reabsorbed in the proximal and distal nephron and this perpetuates the metabolic alkalosis until the fluid balance is restored with intravenous (IV) fluids.

Time taken: 5 hrs 18 mins 58 secs

Work Smart Session - MRCP Part 1

Question: 87 of 100

Which of the following concerning renal blood flow is true?

(Please select 1 option)

○	Can be measured using the Fick principle ← This is the correct answer
○	Is decreased in response to hypoxia
○	Is 40% of the cardiac output at rest
○	Is higher in the medulla than the cortex
◉	Is increased when renal nerves are stimulated ✕ Incorrect answer selected

Renal blood flow (RBF) is approximately 25% of cardiac output.

The 'Fick principle' can be used to estimate RBF through clearance.

RBF is higher in the cortex than medulla as one might expect with the increasing glomeruli in this region.

Sympathetic stimuli produce vasoconstriction and RBF should be increased in response to hypoxia.

Time taken: 5 hrs 20 mins 13 secs

Work Smart Session - MRCP Part 1

Question: 88 of 100

Which one of the following is true concerning antidiuretic hormone (ADH)?

(Please select 1 option)

◉	Carbamazepine potentiates its release ✓ Correct
○	Ethanol potentiates its release
○	It circulates in the blood bound to neurohypophysin
○	It is a cyclic octapeptide
○	It is synthesised in the posterior pituitary

ADH is a nonapeptide manufactured in the paraventricular and supra-optic nuclei of the hypothalamus and released from the posterior pituitary.

It acts on the collecting ducts improving water permeability and hence water retention.

Carbamazepine as well as other agents such as thiazides and selective serotin reuptake inhibitors (SSRIs) may potentiate its release.

Ethanol usually inhibits release.

Question: 89 of 100

Which of the following is a feature of pseudohypoparathyroidism?

(Please select 1 option)

○	Increased urinary phosphate and cAMP with PTH infusion
○	Low serum calcium and high serum phosphate
○	Low serum calcium and low serum phosphate
○	Low serum PTH
○	Shortened second and third metacarpals

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Time taken: 5 hrs 20 mins 42 secs

Work Smart Session - MRCP Part 1

Question: 89 of 100

Which of the following is a feature of pseudohypoparathyroidism?

(Please select 1 option)

○	Increased urinary phosphate and cAMP with PTH infusion
◉	Low serum calcium and high serum phosphate ✓ Correct
○	Low serum calcium and low serum phosphate
○	Low serum PTH
○	Shortened second and third metacarpals

The biochemistry shows a hypocalcaemia with hyperphosphataemia being usual but elevated parathyroid hormone (PTH) due to resistance to PTH.

This is due to mutation of the PTH receptor with abnormality of the Gsalpha subunit with reduced cyclic adenosine monophosphate (cAMP) production following a PTH infusion.

There are associated phenotypic signs including short stature, low IQ and shortened fourth and fifth metacarpals.

Potassium	4.9 mmol/l	(3.5-5)
Creatinine	189 µmol/l	(60-120)
ESR	62	(<10)
Urine	Blood++ Protein ++	

Which of the following is the most likely diagnosis?

(Please select 1 option)

○	Alport's syndrome
◉	Churg-Strauss syndrome ✓ Correct
○	IgA nephropathy
○	Post-streptococcal glomerulonephritis
○	Wegener's granulomatosis

The history of rapidly worsening symptoms of asthma, accompanied by hypertension, raised creatinine and blood and proteinuria are features of Churg-Strauss.

Churg-Strauss is a small and medium sized artery vasculitis. p-ANCA is positive in 70% of patients.

High dose steroids with the addition of cyclophosphamide or azathioprine are standard therapy for the condition.

With treatment the one year survival rate for Churg-Strauss is 90%; 62% at five years.

Question: 9 of 100

A 14-year-old boy is referred by the practice nurse for follow up with you. He was brought by his mother to see the practice nurse because of progressive hearing loss.

Examination and basic investigations revealed nothing of note, apart from haematuria detected on routine urine testing. Apparently he has an 18-year-old brother who also suffers from deafness and has mild renal impairment.

Investigations show

Haemoglobin	13.0 g/dl	(13.5-18)
White cell count	7.1 x 10^9/l	(4-10)
Platelets	199 x 10^9/l	(150-400)
Sodium	140 mmol/l	(134-143)
Potassium	4.7 mmol/l	(3.5-5)
Creatinine	110 µmol/l	(60-120)
ESR	8	(<10)
Urine	Blood +	

Which of the following is the most likely diagnosis?

(Please select 1 option)

- ○ Alport's syndrome
- ○ Autosomal dominant polycystic kidney disease
- ○ IgA nephropathy
- ○ Membranous nephropathy
- ○ Minimal change disease

Question: 90 of 100

Which of the following features would be expected in acute tubular necrosis?

(Please select 1 option)

○	Creatinine clearance would be expected to be normal one year after the initial insult
○	Heavy proteinuria on urinalysis
○	Red cell casts on urinalysis
○	Urine plasma osmolality ratio is more than 1:1
◉	Urine sodium concentration greater than 30 mmol/l ✓ Correct

Red cell casts suggest nephritis and normalisation of the creatinine clearance occurs in only 40% of cases one year later.

Proteinuria, usually mild, is common with granular casts found on urinalysis.

The urine sodium concentration is typically above 30 mmol/l and osmolality ratio <1:1.

Time taken: 5 hrs 22 mins 16 secs

Work Smart Session - MRCP Part 1

Question: 91 of 100

A 70-year-old female is admitted 12 hours after taking an overdose of aspirin.

Investigations revealed:

Serum sodium	138 mmol/l	(137-144)
Serum potassium	5.9 mmol/l	(3.5-4.9)
Serum bicarbonate	14 mmol/l	(20-28)
Serum urea	18.1 mmol/l	(2.5-7.5)
Serum creatinine	238 mol/l	(60-110)
Serum salicylate	1120 mg/l	(8)

What is the most appropriate treatment of this patient?

(Please select 1 option)

- ○ Haemodialysis
- ○ Haemofiltration
- ○ Intravenous sodium bicarbonate
- ○ Peritoneal dialysis
- ○ Urine alkalinisation

Serum urea	18.1 mmol/l	(2.5-7.5)
Serum creatinine	238 mol/l	(60-110)
Serum salicylate	1120 mg/l	(8)

What is the most appropriate treatment of this patient?

(Please select 1 option)

- ◉ Haemodialysis ✓ Correct
- ○ Haemofiltration
- ○ Intravenous sodium bicarbonate
- ○ Peritoneal dialysis
- ○ Urine alkalinisation

This patient is at major risk of aspirin toxicity as reflected by the excessive aspirin concentration and appears to have developed acute renal failure - she is acidotic with an elevated potassium.

Bicarbonate is recommended as a supportive therapy but in this patient, haemodialysis is the treatment of choice. The latter is advised when the plasma-salicylate concentration is greater than 700 mg/litre (5.1 mmol/litre) or in the presence of severe metabolic acidosis as recommended within the BNF poisons section.

There is nothing wrong with haemofiltration it just removes the toxin more slowly.

Read more (very detailed) about haemofiltration vs. haemodialysis in poisoning (pdf).

Question: 92 of 100

The following are complications of nephrotic syndrome with the exception of:

(Please select 1 option)

○	Accelerated hypertension ← This is the correct answer
○	Acute renal failure
◉	Hypocalcaemia ✕ Incorrect answer selected
○	Pneumococcal infection
○	Venous thrombosis

Complications also include hyperlipidaemia, protein malnutrition and loss of binding proteins in urine.

Nephrotic syndrome is likely to be associated with hypocalcaemia (vitamin D binding protein and vitamin D lost in nephrotic urine) and hypovolaemia (low blood pressure).

Which of the following is least likely with the HLA complex?

(Please select 1 option)

○	CD4 T cells recognise antigen when co-presented with MHC class II
○	CD8 T cells recognise antigen when co-presented with major histocompatibility complex (MHC) class I
○	HLA matching is more important in kidney transplantation than liver transplantation
○	Multiple sclerosis is associated with HLA DR2
◉	Polymorphisms occur in class I, but not class II, MHC genes ✓ Correct

Polymorphisms occur in both class I and II genes.

Cytotoxic T cells express the molecule CD8 on the cell surface and only recognise antigen when presented by the T cell receptor (TCR) in conjunction with class I MHC.

T helper cells express CD4 on the cell surface and only recognise antigen when presented by TCR and class II MHC.

T helper cells are divided into Th1 and Th2 depending on function and cytokines released:

- Th1 cells secrete IL-2 and interferon-gamma and are involved in stimulating a cytotoxic immune response
- Th2 cells secrete IL-4, IL-5, IL-10 and stimulate a humoral (antibody) response by B cells.

Liver allografts are less immunogenic than kidney grafts.

Which of the following is correct in asymptomatic chronic renal failure (CRF)?

(Please select 1 option)

○	Decrease in blood pressure accompanied by increase in extracellular fluid
○	Increase serum [alkaline phosphotase] mainly due to liver isoenzyme
○	Serum ionised [calcium] is normal ← This is the correct answer
◉	Serum [phosphate] characteristically increased before GFR falls to 30 ml/min ✕ Incorrect answer selected
○	There is increase in tubular excretion of urate

Urate retention is common feature in CRF.

Total serum [calcium] is reduced or at lower limits of normal but ionised [calcium] is normal unless steps are taken to treat acidosis actively, for example, with sodium bicarbonate.

Plasma phosphate and chloride are almost always raised.

Hyperphosphataemia occurs when glomerular filtration rate [GFR] falls less than 30 ml/min.

Increased bone alkaline phosphotase reflects osteodystrophy.

Hypertension is due largely to salt and water retention, and also overactivity of renin angiotensin systems.

Which of the following is true concerning metastatic calcification in chronic renal failure (CRF)?

(Please select 1 option)

◉	Characteristically caused by calcium oxalate deposition ✗ Incorrect answer selected
○	Decreased by vitamin D
○	Increased prevalence with time on haemodialysis ← This is the correct answer
○	Rapidly reversed in all sites after parathyroidectomy
○	Unaffected by time on CAPD

CRF is associated with

- Low serum calcium
- Hyperphosphataemia
- Increased parathyroid hormone (PTH)
- Reduced intestinal calcium absorption and
- Raised alkaline phosphatase.

Parathyroidectomy improves extraskeletal calcification, but vascular calcification improves less than periarticular calcification.

Metastatic calcification is due mainly to calcium phosphate deposition, although CRF managed with dialysis is the commonest cause of secondary oxalosis (acute arthritis of small joints with digital calcific deposits). Prolonged treatment with vitamin D (hence hypercalcaemia and hyperphosphataemia) increases extraskeletal calcification.

Work Smart Session - MRCP Part 1

Question: 96 of 100

A 63-year-old male recently admitted with sepsis is noted to have a urine output of approximetely 20 mls per hour.

The oliguria is more likely to be due to prerenal failure than intrinsic renal failure if which of the folllowing is correct?

(Please select 1 option)

○	A blood pressure of 150/90 and good tissue perfusion.
○	A urine free of red blood cells or casts
○	A urine:plasma urea ratio <3
○	Urine osmolality <350 mOsm/l
○	Urinary sodium >10mmol/l

Submit answer | Skip question | Tag Question | Remove question

- Help

(Please select 1 option)

○	A blood pressure of 150/90 and good tissue perfusion.
○	A urine free of red blood cells or casts ← This is the correct answer
○	A urine:plasma urea ratio <3
○	Urine osmolality <350 mOsm/l
◉	Urinary sodium >10mmol/l ✕ Incorrect answer selected

Oliguria is defined as < 400 ml urine/day.

Red cell casts present in

- Acute glomerulonephritis
- Renal vasculitis
- Accelerated hypertension and
- Interstitial nephritis.

Pre-renal failure is renal dysfunction due to hypoperfusion (urinary sodium <20, urine osmolality >500, urine/plasma ratio >8, and urine/plasma creatinine >40).

Acute tubular necrosis is acute renal failure due to circulatory compromise and/or nephrotoxins (urinary sodium >40, urine osmolality <350, urine/plasma ratio <3, and urine/plasma creatinine <20).

Work Smart Session - MRCP Part 1

Question: 97 of 100

Are the following true concerning anti-neutrophilic cytoplasmic autoantibodies?

(Please select 1 option)

○	ANCA positive glomerulonephritis characteristically causes nephrotic syndrome
○	Cause neutropenia in SLE
○	Increased in systemic lupus erythematosus (SLE)
○	Positive only in Wegener's syndrome associated with renal disease
○	Present in inflammatory bowel disease

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Time taken: 5 hrs 37 mins 12 secs

Work Smart Session - MRCP Part 1

Question: 97 of 100

Are the following true concerning anti-neutrophilic cytoplasmic autoantibodies?

(Please select 1 option)

○	ANCA positive glomerulonephritis characteristically causes nephrotic syndrome
○	Cause neutropenia in SLE
○	Increased in systemic lupus erythematosus (SLE)
○	Positive only in Wegener's syndrome associated with renal disease
◉	Present in inflammatory bowel disease ✓ Correct

Eighty five percent of untreated subjects with Wegener's will have circulating anti-neutrophil cytoplasmic antibody (cANCA) and those with limited disease are less likely to have positive serology.

Perinuclear anti-neutrophil cytoplasmic antibody (pANCA) is present in approximately 70% with ulcerative colitis and less than 20% of Crohn's patients.

Neither p nor c-ANCA is typical of SLE.

Initial renal damage causes proteinuria (focal proliferative glomerulonephritis) but renal function can deteriorate rapidly with development of acute focal necrotising glomerulonephritis.

Time taken: 5 hrs 37 mins 12 secs

Work Smart Session - MRCP Part 1

Question: 98 of 100

A patient with end stage renal disease is receiving haemodialysis and erythropoietin.

Which of the following does erythropoietin therapy cause?

(Please select 1 option)

○	Benign intracranial hypertension
○	Hypotension
○	Myositis
○	Osteoporosis
○	Seizures

Submit answer | Skip question | Tag Question | Remove question

○	Osteoporosis
◉	Seizures ✓ Correct

Hypertension is a frequent problem associated with erythropoietin and may induce seizures.

A particular symptom is the onset of sudden stabbing migraine-like headache and should raise awareness to the possibility of hypertensive crisis.

Other adverse effects of treatment with erythropoietin include:

- hyperkalaemia in uraemic patients

- increased packed cell volume (PCV) (especially with misuse by normal individuals)

- thrombocythaemia

- shunt thrombosis

- induction of iron deficiency

- skin rashes

- urticaria and

- flu-like illness.

Time taken: 5 hrs 40 mins 11 secs

Work Smart Session - MRCP Part 1

Question: 99 of 100

In which of the following circumstances would the treatment of anaemia with erythropoetin still be expected to be effective?

(Please select 1 option)

- Aluminium toxicity
- Folate deficiency
- Hyperkalaemia
- Infection
- Iron deficiency

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

In which of the following circumstances would the treatment of anaemia with erythropoetin still be expected to be effective?

(Please select 1 option)

◉	Aluminium toxicity ✗ Incorrect answer selected
○	Folate deficiency
○	Hyperkalaemia ← This is the correct answer
○	Infection
○	Iron deficiency

Epoetin (recombinant human erythropeitin) is used

- In chronic renal failure
- To shorten the period of anaemia in those receiving platinum-based chemotherapy and
- Prevention of anaemia in premature babies with low birth weight.

Its efficacy may be impaired in certain circumstances particularly with iron deficiency but also with aluminium toxicity, folate deficiency and infection. In the latter the switch to the acute phase proteins impairs its function.

Its efficacy is unimpaired in hyperkalaemia.

Creatinine	110 µmol/l	(60-120)
ESR	8	(<10)
Urine	Blood +	

Which of the following is the most likely diagnosis?

(Please select 1 option)

◉	Alport's syndrome ✓ Correct
○	Autosomal dominant polycystic kidney disease
○	IgA nephropathy
○	Membranous nephropathy
○	Minimal change disease

Alport's syndrome comprises

- Sensorineural hearing loss
- Progressive renal failure
- Haematuria
- Ocular abnormalities including cataract formation.

The condition is often associated with an X linked dominant inheritance pattern and hence males are more severely affected.

Prevalence is around 1 in 5000, and the condition occurs because of type 4 collagen mutations. Deafness usually occurs before the onset of renal failure, which is related itself to progressive nephritis.

Rigorous control of hypertension may delay the onset of end stage renal failure, which is seen in 90% of patients with Alport's by the age of 40 years.

Work Smart Session - MRCP Part 1

Question: 10 of 100

A 36-year-old female presents with a six month history of having problems sleeping at night. She has been woken on numerous occasions by her legs which are irritable and feel that they are being tugged. She needs to keep moving them. This urge lasts for variable periods and she finds little relief from rubbing the legs. No abnormalities are noted on examination of her legs.

Which of the following is the most appropriate treatment for this patient?

(Please select 1 option)

- Amitriptyline
- Gabapentin
- Psychiatric referral
- Ropinirole
- Venlafaxine

Work Smart Session - MRCP Part 1

Question: 100 of 100

A 24-year-old female presents with vague frontal headaches and visual disturbance.

She has a past history of acne for which she is receiving treatment. Examination reveals her to be obese with a blood pressure of 110/70 mmHg. There is absence of the central retinal vein pulsation on fundoscopic examination.

Which of the following drugs account for these findings?

(Please select 1 option)

○	Ampicillin
○	Dianette
○	Erythromycin
○	Isotretinoin
○	Topical tetracycline

Submit answer | Skip question | Tag Question | Remove question

Question: 100 of 100

A 24-year-old female presents with vague frontal headaches and visual disturbance.

She has a past history of acne for which she is receiving treatment. Examination reveals her to be obese with a blood pressure of 110/70 mmHg. There is absence of the central retinal vein pulsation on fundoscopic examination.

Which of the following drugs account for these findings?

(Please select 1 option)

○	Ampicillin
○	Dianette ← This is the correct answer
○	Erythromycin
◉	Isotretinoin ✕ Incorrect answer selected
○	Topical tetracycline

Dianette, like any oral contraceptive, may be associated with benign intracranial hypertension (BIH).

Topical tetracycline is not associated with BIH.

Rarely BIH has been associated with isotretinoin but usually in combination with a tetracycline.

Which of the following is the most appropriate treatment for this patient?

(Please select 1 option)

○	Amitriptyline
○	Gabapentin
○	Psychiatric referral
◉	Ropinirole ✓ Correct
○	Venlafaxine

This patient has features of restless legs syndrome (RLS). Typically there is an uncomfortable sensation in the legs and a feeling of needing to move them.

The exact aetiology is unknown. Although no specific tests exist for the diagnosis it is based on the International Restless Legs Syndrome Study Group four basic criteria for diagnosing RLS:

(1) a desire to move the limbs, often associated with paresthesias or dysesthesias

(2) symptoms that are worse or present only during rest and are partially or temporarily relieved by activity

(3) motor restlessness, and

(4) nocturnal worsening of symptoms.

Treatment depends on the severity of the problem and the most appropriate treatment here would be ropinirole, which is the only agent licensed for this purpose.

Time taken: 21 mins 37 secs

Work Smart Session - MRCP Part 1

Question: 11 of 100

A 55-year-old man presents with neck pain.

One week previously he had attended for a sigmoidoscopy and was given intravenous sedation during this procedure. One day prior to admission his neck and shoulders had become stiff.

On examination, the temperature was 38.0°C, blood pressure was 100/60 mmHg and heart rate 100 bpm.

There were absent biceps jerks and weakness of trapezius, deltoid and triceps bilaterally. The cranial nerves and lower limbs were normal.

There was a soft systolic murmur, and the chest was clear.

Which examination is likely to confirm the diagnosis?

(Please select 1 option)

○	Cervical spine X-ray
○	CT head
○	Echocardiography
○	Lumbar puncture
○	MRI neck

Submit answer | Skip question | Tag Question | Remove question

Which examination is likely to confirm the diagnosis?

(Please select 1 option)

○	Cervical spine X-ray
○	CT head
◉	Echocardiography ✕ Incorrect answer selected
○	Lumbar puncture
○	MRI neck ← This is the correct answer

The features suggest a paraspinal abscess affecting C4-C6 given the neurological findings.

The investigation of the patient should include all of the above tests.

Paraspinal abscess is often associated with infection in an intravenous (IV) line, which may or may not be apparent as cellulites.

Neurological signs, once apparent, should lead to rapid investigation as once they are present recovery of strength may be slow, or not at all.

A magnetic resonance imaging (MRI) of the neck should delineate the anatomy of the abscess, which will not be seen on a computerised tomography (CT) scan of the head.

However, given that these lesions are usually due to seeding of *Staphylococcus aureus*, endocarditis is a possibility.

Cerebral spinal fluid (CSF) should show an elevated protein with raised white cells, and a low/normal glucose.

Time taken: 25 mins 42 secs

Work Smart Session - MRCP Part 1

Question: 12 of 100

A 59-year-old female pub landlady presents with acute, severe lumbar back pain.

There is no history of orthopaedic problems and until this event, she had been in perfect health.

The patient complains of parasthesiae in the lower limbs, and on further questioning has not voided urine since the onset of the pain.

Neurological examination reveals weakness (3/5 of both lower limbs, loss of sensation in L4, L5 and S1. Vibration sensation and joint position sensation is preserved. Reflexes in the ankles and knees are absent, and the plantar response is equivocal.

The blood pressure is 158/68 mmHg, heart rate 95 bpm, temperature 36.9°C and ECG shows normal sinus rhythm with no ischaemic changes.

The remainder of the examination is normal.

Which of the following should be undertaken next for this patient?

(Please select 1 option)

○	CT head
○	Duplex scan of aorta
○	MRI spinal cord
○	Rectal examination
○	USS abdomen

○	Duplex scan of aorta
◉	MRI spinal cord ✕ Incorrect answer selected
○	Rectal examination ← This is the correct answer
○	USS abdomen

The diagnosis here is spinal stroke otherwise known as spinal artery thrombosis.

The acute presentation of the symptoms is suggestive of a vascular event.

The easiest and safest way to make the diagnosis is magnetic resonance imaging (MRI) of the spinal cord. However, loss of rectal tone is extremely supportive of the diagnosis.

Bladder dysfunction is also suggested by the lack of urine.

Guillan-Barre and acute inflammatory demyelinating polyneuropathy (AIDP) are important differentials here, but do not usually cause sphincter dysfunction. The sensory loss is more suggestive of a peripheral neuropathy, in that there is distal sensory loss and no sensory level.

Spinal cord compression is also an important differential and the so-called 'surgical causes', for example, epidural abscess, spinal tumour, and granuloma.

The fact that this patient is apyrexial is thus significant.

A rectal examination is an important discriminator in the clinical findings and should be undertaken prior to MRI.

A computerised tomography (CT) scan of the head may be undertaken out of hours, prior to an MRI, as lumbar puncture and cerebrospinal fluid (CSF) examination are vital examinations in the work up of this patient.

Time taken: 28 mins 5 secs

Work Smart Session - MRCP Part 1

Question: 13 of 100

A 40-year-old male presents to casualty with weakness and parasthesiae of the right arm and leg. The symptoms developed 12 hours after the onset of a piercing left sided headache. There is no neck stiffness, but there is a pain in the left side of the neck and occiput. Kernig's sign is negative. The patient is afebrile, and blood results are normal.

What is the investigation of choice?

(Please select 1 option)

- Contrast arteriography
- CT head
- Duplex scanning of the neck vessels
- Lumbar puncture
- MRI brain

Submit answer | Skip question | Remove Tag | Remove question

occiput. Kernig's sign is negative. The patient is afebrile, and blood results are normal.

- Help

What is the investigation of choice?

(Please select 1 option)

○	Contrast arteriography ← This is the correct answer
◉	CT head ✕ Incorrect answer selected
○	Duplex scanning of the neck vessels
○	Lumbar puncture
○	MRI brain

Ischaemic neurological features (transient or completed strokes) are found in 30-80% of presenting patients presenting with carotid artery dissection. Pulsatile tinnitus is common, as well as syncope and amaurosis fugax. Headache is commonly ipsilateral to the side of the carotid dissection, and recurrence of the headache suggests extension or recurrence of the dissection. The most accurate study and the current gold standard for diagnosis of carotid artery dissection, contrast arteriography should be strongly considered if neurological findings are incompatible with the findings of CT head, there is mono or hemiparesis with normal mental state, signs or history of major cervical trauma with abnormal neurology, or basilar skull fracture in a patient with altered mental status. In the absence of arteriography, Duplex scanning or MRI with MRA may be considered the next best tests. Limitations of duplex scanning include difficulties of scanning the distal internal carotid artery, detecting emboli, and evaluating intracranial arteries. The combination of MRI and MRA is more reliable in detecting dissection than either modality alone. Lumbar puncture results may be misleading, as xanthochromia may occur when a haematoma propagates. This rare finding may lead to a diagnosis of subarachnoid hemorrhage and failure to perform further carotid workup.

Time taken: 37 mins 20 secs

Work Smart Session - MRCP Part 1

Question: 14 of 100

A 78-year-old male is brought to the Emergency Department and has a witnessed seizure in the resuscitation room.

His blood glucose is recorded as 1.0 mmol/l. He does not have diabetes, and has no other significant past medical history.

He is given 50 ml of 50% dextrose and he slowly recovers over the next one hour. A serum cortisol concentration later returns as 800 nmol/l (120-600).

Which of the following would be the most relevant investigation for this man?

(Please select 1 option)

- Chest x ray
- CT head scan
- Electrocardiogram
- Prolonged 72 hour fast
- Short synacthen test

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

800 nmol/l (120-600).

Which of the following would be the most relevant investigation for this man?

(Please select 1 option)

○	Chest x ray
○	CT head scan
○	Electrocardiogram
◉	Prolonged 72 hour fast ✓ Correct
○	Short synacthen test

The historical and biochemical evidence here suggests a diagnosis of spontaneous hypoglycaemia, and the most likely cause would be an insulinoma. However, one would wish to exclude possible drug administration and although not mentioned here, a sulphonylurea screen should be undertaken.

He has presented with symptomatic hypoglycaemia, is not diabetic and therefore should not have received insulin or a sulphonylurea.

There is nothing to suggest alcohol or drug misuse. Similarly, there is nothing to suggest sepsis.

However, to prove a diagnosis of spontaneous hypoglycaemia, a prolonged fast is required and should he develop hypoglycaemia, measurement of insulin and C-peptide will be needed to confirm the diagnosis.

The appropriate cortisol response during his hypoglycaemic episode (cortisol 800) excludes hypoadrenalism.

Work Smart Session - MRCP Part 1

Question: 15 of 100

A 74-year-old retired newsagent presents with left-sided weakness. The weakness had developed slowly over the preceding six hours.

On examination he has a left hemiparesis and left facial weakness. His blood pressure is 180/100 mmHg and a heart rate 90 bpm regular. The patient's wife tells you that he has been choking on fluids since the weakness developed.

What should be your first action out of the following options?

(Please select 1 option)

- CT head
- IV streptokinase
- NG tube placement
- Nifedipine 10 mg stat
- Test his swallow with a glass of water

Submit answer | Skip question | Tag Question | Remove question

- Help

regular. The patient's wife tells you that he has been choking on fluids since the weakness developed.

What should be your first action out of the following options?

(Please select 1 option)

○	CT head
○	IV streptokinase
○	NG tube placement
○	Nifedipine 10 mg stat
◉	Test his swallow with a glass of water ✓ Correct

National stroke guidelines suggest that the risk of aspiration after acute cerebrovascular accident (CVA) should be assessed immediately on admission. If the patient spluttered, aspirated, coughed or choked on fluid that you administered then you should make him nil by mouth and perhaps place an nasogastric (NG) tube until review by the nutritionists/SALT team.

If you were considering this gentleman for thrombolysis then a CT would need to be carried out urgently (or an MRI!).

Thrombolysis of strokes is a developing service and is not common practice as yet but it is useful to consider this option in an acute CVA which presents early (that is, less than three hours). It is likely that we will be thrombolysing selected patients in the near future.

Hypertension post-CVA serves a protective function and anti-hypertensives should usually be avoided in the first week.

Work Smart Session - MRCP Part 1

Question: 16 of 100

A 65-year-old male presents with bilateral leg pain.

There is no relevant past medical history, and no excess alcohol use. Both knee reflexes are reduced.

Fasting glucose is 6.5 mmol/L.

Which is the next investigation most likely to confirm the diagnosis?

(Please select 1 option)

○	B12 and folate
○	Chest x ray
○	CSF examination
◉	MRI spine
○	Oral glucose tolerance test

Submit answer | Skip question | Tag Question | Remove question

Question: 16 of 100

A 65-year-old male presents with bilateral leg pain.

There is no relevant past medical history, and no excess alcohol use. Both knee reflexes are reduced.

Fasting glucose is 6.5 mmol/L.

Which is the next investigation most likely to confirm the diagnosis?

(Please select 1 option)

○	B12 and folate
○	Chest x ray
○	CSF examination
○	MRI spine
◉	Oral glucose tolerance test ✓ Correct

The suggestion of bilateral leg pain, weakness and reduced knee reflexes with an impaired fasting glucose concentration suggests a diagnosis of diabetic amyotrophy. This is confirmed with a formal OGTT.

Diabetic amyotrophy is not uncommonly a presenting feature of diabetes in the elderly. The features are of an asymmetrical but bilateral quadriceps wasting and weakness with diminished reflexes.

Work Smart Session - MRCP Part 1

Question: 17 of 100

A 69-year-old male presents with sudden onset weakness of his legs associated with urinary retention. Five years previously he was diagnosed with sigmoid colonic carcinoma which was surgically resected.

Examination revealed a flaccid paraparesis of the legs with absent tendon reflexes and plantar responses. Pinprick and temperature sensations were absent to T12 level, but there was a relative sparing of light touch and joint position sensation.

What is the most likely diagnosis?

(Please select 1 option)

- Anterior spinal artery occlusion
- Intramedullary spinal cord metastasis
- Spinal cord compression due to vertebral metastasis
- T11/12 central disc prolapse
- Transverse myelitis

Submit answer | Skip question | Tag Question | Remove question

diagnosed with sigmoid colonic carcinoma which was surgically resected.

Examination revealed a flaccid paraparesis of the legs with absent tendon reflexes and plantar responses. Pinprick and temperature sensations were absent to T12 level, but there was a relative sparing of light touch and joint position sensation.

What is the most likely diagnosis?

(Please select 1 option)

◉	Anterior spinal artery occlusion ✓ Correct
○	Intramedullary spinal cord metastasis
○	Spinal cord compression due to vertebral metastasis
○	T11/12 central disc prolapse
○	Transverse myelitis

The lesion is involving the anterior two thirds of the spinal cord which spares light touch, vibration and position sense, but causes loss of pain and temperature sensation distally.

The diagnostic possibilities therefore include anterior spinal artery occlusion, which is rare, and intramedullary spinal cord metastasis.

The condition has developed quite suddenly, which is the key and supports a vascular event.

Intramedullary spinal cord lesions are also rare, and vertebral metastasis causing cord compression occurs more commonly; however the clinical signs suggest sparing of the dorsal columns.

A 55-year-old male is admitted with vomiting.

He has a long history of alcohol abuse, appears slightly jaundiced and is dishevelled and unkempt. He was started on an intravenous glucose infusion and diazepam and he symptomatically improved.

One day later he becomes confused, develops vomiting, diplopia and is unable to stand.

What is the most likely diagnosis?

(Please select 1 option)

○	Benzodiazepine intoxication
○	Delirium tremens
○	Hepatic encephalopathy
◉	Subdural haematoma ✕ Incorrect answer selected
○	Vitamin B deficiency ← This is the correct answer

This patient is manifesting signs of Wernicke's encephalopathy with confusion, oculomotor signs and ataxia affecting gait and stance. Wernicke's encephalopathy is a medical emergency, requiring urgent intravenous thiamine.

The episode has been precipitated by intravenous dextrose administration which has exhausted his vitamin B reserves, hence B vitamins must be administered to all alcoholic patients requiring dextrose.

Question: 19 of 100

An 85-year-old woman with diabetes mellitus presented with sudden onset of wild flinging movements of the left arm which disappeared during sleep.

What is the most likely explanation?

(Please select 1 option)

◉	Contralateral subthalamic nucleus infarction ✓ Correct
○	Focal motor seizures
○	Hypoglycaemia
○	Ipsilateral caudate nucleus infarction
○	Ipsilateral cerebellar infarction

This is hemiballismus, and in a diabetic patient is likely to be due to a vascular event in the contralateral subthalamic nucleus.

Work Smart Session - MRCP Part 1

Question: 1 of 100

A 75-year-old woman presents with a two month history of episodic loss of vision in her right eye. Her electrocardiogram was normal and carotid ultrasound reveal a 50% stenosis of the right internal carotid artery.

What is the most appropriate treatment for this patient?

(Please select 1 option)

◉	Aspirin ✓ Correct
○	Carotid endarterectomy
○	Dipyridamole
○	Prednisolone
○	Warfarin

The patient experienced transient ischaemic attacks (TIAs) of the form of amaurosis fugax due to carotid artery stenosis.

Carotid endarterectomy is only indicated if the stenosis is 70-99%.

Aspirin is the treatment of choice and good control of all vascular risk factors.

Warfarin is not indicated unless the patient is in atrial fibrillation (AF).

Work Smart Session - MRCP Part 1

Question: 2 of 100

A 60-year-old male is referred with episodes of severe vertigo which may last up to four hours and are associated with vomiting and pain in the right ear.

On examination during an attack he is noted to have right horizontal nystagmus together with mild right-sided sensorineural deafness.

Which one of the following is the most likely diagnosis?

(Please select 1 option)

- Acoustic neuroma
- Benign positional vertigo
- Labyrinthitis
- Ménière's disease
- Vertebrobasilar ischaemic attacks

Work Smart Session - MRCP Part 1

Question: 20 of 100

Which one of the following statements is correct?

(Please select 1 option)

- The abducens nerve supplies the lacrimal gland
- The facial nerve supplies the parotid salivary gland
- The oculomotor nerve supplies the dilator pupillae muscle
- The trochlear nerve supplies the superior rectus muscle
- The vagus nerve supplies the palatal muscles

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Question: 20 of 100

Which one of the following statements is correct?

(Please select 1 option)

○	The abducens nerve supplies the lacrimal gland
○	The facial nerve supplies the parotid salivary gland
○	The oculomotor nerve supplies the dilator pupillae muscle
○	The trochlear nerve supplies the superior rectus muscle
◉	The vagus nerve supplies the palatal muscles ✓ Correct

The lacrimal gland is supplied by the facial nerve.

The glossopharyngeal nerve supplies the parotid salivary gland controlling salivary secretions.

The oculomotor nerve carries parasympathetic efferents to the sphincter pupillae muscle.

The optic nerve carries sympathetic postganglionic fibres to the dilator pupillae muscle.

The trochlear nerve supplies the superior oblique muscle.

The occulomotor nerve innervates the superior rectus.

Work Smart Session - MRCP Part 1

Question: 21 of 100

Hearing losses of a mild degree or worse (>25dB) are present in around 10% of the population. As the population ages, the percentage of people with hearing loss also increases.

Which of the following age-percentage loss combinations is not correct for the general population?

(Please select 1 option)

○	At birth approximately 0.3% affected
○	Aged 50-59: approximately 10% affected
○	Aged 60-69: approximately 25% affected
○	Aged 70-79: approximately 50% affected
◉	Aged 80-89: approximately 50% affected ✓ Correct

Percentage of the population with a significant hearing loss increases with each decade of life.

For the 80-89-year-old age group, around 70-80% of them will have a degree of hearing loss >25dB.

Work Smart Session - MRCP Part 1

Question: 22 of 100

A 30-year-old male presents with a week history of right arm weakness. Originally the problem began with severe pain in the neck which radiated into the right shoulder, which was followed by weakness.

Examination revealed winging of the right scapula with weakness of right shoulder abduction and elbow extension. There was some sensory loss over the lateral aspect of the right shoulder and right triceps reflex was absent.

What is the most likely diagnosis?

(Please select 1 option)

- C7 entrapment radiculopathy
- Central C5/6 disc prolapse
- Neuralgic amyotrophy
- Suprascapular nerve entrapment
- Traction of lateral cord of brachial plexus

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

which radiated into the right shoulder, which was followed by weakness.

Examination revealed winging of the right scapula with weakness of right shoulder abduction and elbow extension. There was some sensory loss over the lateral aspect of the right shoulder and right triceps reflex was absent.

What is the most likely diagnosis?

(Please select 1 option)

○	C7 entrapment radiculopathy
◉	Central C5/6 disc prolapse ✕ Incorrect answer selected
○	Neuralgic amyotrophy ← This is the correct answer
○	Suprascapular nerve entrapment
○	Traction of lateral cord of brachial plexus

Neuralgic amyotrophy is a brachial plexopathy (usually upper brachial plexus) usually preceded by an infective picture.

It usually presents with severe pain for days to weeks followed by weakness and sensory loss over the corresponding territory of the brachial plexus (more commonly C5-7).

It is a self-limiting condition but recovery may be slow (years).

Work Smart Session - MRCP Part 1

Question: 23 of 100

A 55-year-old woman with multiple sclerosis is treated for severe hip adductor muscle spasticity and two days later develops double vision.

Which one of the following treatments is she likely to have been given?

(Please select 1 option)

- ○ Botulinum toxin
- ○ Dantrolene
- ○ Intrathecal baclofen
- ○ Oral baclofen
- ○ Tizanidine

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Question: 23 of 100

A 55-year-old woman with multiple sclerosis is treated for severe hip adductor muscle spasticity and two days later develops double vision.

Which one of the following treatments is she likely to have been given?

(Please select 1 option)

○	Botulinum toxin ← This is the correct answer
◉	Dantrolene ✕ Incorrect answer selected
○	Intrathecal baclofen
○	Oral baclofen
○	Tizanidine

Botulinum toxin is the treatment of choice for focal dystonia (such as torticollis, and hemi-facial spasm) and focal dystonia.

The primary action of the toxin is to block acetylcholine release at the neuromuscular junction and so to produce muscle weakness.

Occasionally systemic absorption of the toxin can affect distal muscles causing symptoms such as diplopia and dysphagia.

Work Smart Session - MRCP Part 1

Question: 24 of 100

A 28-year-old female, three days post-partum, develops severe headache associated with seizures.

During her pregnancy her blood pressure had been mildly elevated in the third trimester.

On examination, she had a GCS of 15 but was slightly confused and drowsy. Her temperature was 37.5ºC, she had mild nuchal rigidity but neurological examination was otherwise normal.

What is the most likely diagnosis?

(Please select 1 option)

- ○ Bacterial meningitis
- ○ Cortical vein thrombosis
- ○ Eclampsia
- ○ Intracerebral haemorrhage
- ○ Subarachnoid haemorrhage

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

During her pregnancy her blood pressure had been mildly elevated in the third trimester.

On examination, she had a GCS of 15 but was slightly confused and drowsy. Her temperature was 37.5ºC, she had mild nuchal rigidity but neurological examination was otherwise normal.

What is the most likely diagnosis?

(Please select 1 option)

○	Bacterial meningitis
◉	Cortical vein thrombosis ✓ Correct
○	Eclampsia
○	Intracerebral haemorrhage
○	Subarachnoid haemorrhage

Post-partum period is a risk factor of cortical vein and sinus thrombosis.

It typically presents with headache, seizures and focal neurological deficit two to three weeks postpartum (but is also seen earlier).

Other clinical presentations include a benign intercranial hypertension (BIH) type of picture (papilloedema, visual disturbances and headaches) or a subacute encephalopathic picture. Thrombophilia screen should be performed.

Eclampsia typically improves following delivery. The seizures can occur prepartum, intrapartum, or postpartum.

If the seizure occurs postpartum, it usually occurs within the first 24 hours after delivery.

Work Smart Session - MRCP Part 1

Question: 25 of 100

A 35-year-old woman is referred with right eye pain that has deteriorated over the last week.

On examination she had a mild ptosis of the right eye and was aware of diplopia with vertical image separation on looking upwards. She also had weakness of elevation of the right eye.

What is the most likely diagnosis?

(Please select 1 option)

- Cavernous sinus thrombosis
- Graves' ophthalmopathy
- Myasthenia gravis
- Posterior communicating artery aneurysm
- Sphenoid sinusitis

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 35-year-old woman is referred with right eye pain that has deteriorated over the last week.

On examination she had a mild ptosis of the right eye and was aware of diplopia with vertical image separation on looking upwards. She also had weakness of elevation of the right eye.

What is the most likely diagnosis?

(Please select 1 option)

○	Cavernous sinus thrombosis
○	Graves' ophthalmopathy
○	Myasthenia gravis
◉	Posterior communicating artery aneurysm ✓ Correct
○	Sphenoid sinusitis

The signs are consistent with a partial third nerve palsy associated with periorbital pain.

In a young person a posterior communicating artery aneurysm needs to be excluded.

With cavernous sinus thrombosis one should expect some other signs such as periorbital swelling, proptosis, and conjuctival injection.

With Graves' eye disease one should expect proptosis and lid retraction.

Myasthenia gravis does not present with pain.

Time taken: 1 hrs 13 mins 26 secs

Work Smart Session - MRCP Part 1

Question: 26 of 100

A 54-year-old male presents with progressive pins and needles and numbness in both feet which have deteriorated over the last six months.

He has a 10 year history of type 2 diabetes mellitus and had cervical spondylosis for which he underwent surgery eight years ago. He also confessed to drinking approximately 40 units of alcohol weekly.

On examination he had a mild bilateral weakness of foot dorsiflexion, both ankle reflexes were absent and plantar responses were flexor. There was absent sensation to light touch to mid-shin level with loss of joint position sensation in the toes and absent vibration sensation below the hips. He had a marked sensory ataxia and pseudoathetosis of upper limbs. He had no evidence of a retinopathy and urinalysis was normal.

What is the most likely diagnosis?

(Please select 1 option)

○	Alcohol-induced neuropathy
○	Central lumbar disc prolapse
○	Cervical cord compression
○	Diabetic peripheral neuropathy
○	Vitamin B_{12} deficiency

He has a 10 year history of type 2 diabetes mellitus and had cervical spondylosis for which he underwent surgery eight years ago. He also confessed to drinking approximately 40 units of alcohol weekly.

On examination he had a mild bilateral weakness of foot dorsiflexion, both ankle reflexes were absent and plantar responses were flexor. There was absent sensation to light touch to mid-shin level with loss of joint position sensation in the toes and absent vibration sensation below the hips. He had a marked sensory ataxia and pseudoathetosis of upper limbs. He had no evidence of a retinopathy and urinalysis was normal.

What is the most likely diagnosis?

(Please select 1 option)

○	Alcohol-induced neuropathy
○	Central lumbar disc prolapse
○	Cervical cord compression
○	Diabetic peripheral neuropathy
◉	Vitamin B_{12} deficiency ✓ Correct

Diabetic peripheral neuropathy usually goes in parallel with retinopathy and nephropathy.

It is also slowly progressive and affects mainly spinothalamic pathway.

Alcohol induced peripheral neuropathy is also slowly progressive and affects mainly spinothalamic pathway.

Vitamin B_{12} deficiency usually causes a more rapidly progressive neuropathy with dorsal column involvement (joint position and vibration involvement with sensory ataxia and pseudoathetosis of upper limbs).

Question: 27 of 100

A 69-year-old man is admitted with pain and numbness in his right foot following a right hip replacement.

In his past medical history he had been treated for lower backache by his GP.

On examination there was weakness of all movements at the right ankle, with absent right ankle jerk, and sensory impairment on the lateral aspect and sole of the foot.

Where is the most likely site of the lesion?

(Please select 1 option)

○	Femoral nerve
○	Lumbosacral plexus
○	Obturator nerve
○	Sciatic nerve ← This is the correct answer
◉	S1 spinal root ✕ Incorrect answer selected

Sciatic nerve palsy is a known complication of a total hip replacement (as femoral nerve palsy).

It causes global weakness of the ankle due to the involvement of both of its branches: tibial nerve (plantaflexion and inversion) and common peroneal nerve (dorsiflexion and eversion).

The left ankle jerk is absent due to tibial nerve involvement.

Work Smart Session - MRCP Part 1

Question: 28 of 100

A 45-year-old man presented with a three day history of headache and increasing confusion.

On examination he was febrile with marked neck stiffness.

Investigations revealed:

Cerebrospinal fluid analysis (normal ranges are shown in brackets):

White cell count	600/ml (<5)
White cell differential	>90% Neutrophils
Gram stain	Gram-negative diplococci

Which one of the following antibiotics, given intravenously, is the most appropriate treatment?

(Please select 1 option)

- ○ Ampicillin
- ○ Benzylpenicillin
- ○ Cefuroxime
- ○ Ciprofloxacin
- ○ Gentamicin

http://my.onexamination.com/Assessment/Que
Questions Set : REF6301
Hotmail - dr.zahir2009@hotm...

○	Ampicillin
◉	Benzylpenicillin ✓ Correct
○	Cefuroxime
○	Ciprofloxacin
○	Gentamicin

This is clearly a case of meningococcal meningitis. The commonest causes of bacterial meningitis in adults are:

- *Neisseria meningitidis* (Gram negative diplococci)
- *Streptococcus pneumoniae* (Gram positive diplococci).

Treatment of bacterial meningitis

On the basis of Gram stain results:

- Gram stain unavailable or no stainable organisms: Cefotaxime ± ampicillin
- Gram-positive cocci: Cefotaxime + vancomycin
- Gram-positive bacilli: Ampicillin + gentamicin
- Gram-negative cocci: Benzyl penicillin (Penicillin G)
- Gram-negative bacilli: Cefotaxime + gentamicin

On the basis of CSF culture:

- *Streptococcus pneumoniae*
  - If penicillin MIC <0.06 µgrams/mL: Benzyl penicillin (Penicillin G) or cefotaxime
  - If penicillin MIC >0.1 µgrams/ml (that is, penicillin-resistant pneumococcus): Cefotaxime (+ vancomycin if susceptibility to

Question: 29 of 100

A 59-year-old woman presents with polysymptomatology. On examination she has prominent fasciculations.

From which of the following conditions is she unlikely to suffer?

(Please select 1 option)

- Cervical spondylosis
- Motor neurone disease
- Multiple sclerosis
- Spinal muscular atrophy
- Thyrotoxicosis

Submit answer | Skip question | Tag Question | Remove question

A 59-year-old woman presents with polysymptomatology. On examination she has prominent fasciculations.

From which of the following conditions is she unlikely to suffer?

(Please select 1 option)

○	Cervical spondylosis
○	Motor neurone disease
◉	Multiple sclerosis ✓ Correct
○	Spinal muscular atrophy
○	Thyrotoxicosis

Fasciculations suggest lower motor neurone disease. Fasciculations may be seen in otherwise normal individuals with no muscular weakness/atrophy. If pronounced and combined with muscle atrophy they usually signify motor neurone disease (MND).

They may also be seen in diseases that involve

- Spinal cord grey matter
- Lesions of anterior roots
- Peripheral neuropathies.

They may also be seen with severe metabolic disturbance, dehydration, thyrotoxicosis, but not in demyelinating disease of the central nervous system.

Rate this question

☆☆☆☆☆

(Please select 1 option)

○	Acoustic neuroma
○	Benign positional vertigo
◉	Labyrinthitis ✕ Incorrect answer selected
○	Ménière's disease ← This is the correct answer
○	Vertebrobasilar ischaemic attacks

This is a typical history of Ménière's disease.

The attacks are paroxysmal, lasting hours and consist of

- Vertigo
- Vomiting
- Pressure within the ear
- Deafness.

After many attacks the patient may develop irreversible sensorineural deafness (of low frequency).

Prochlorperazine or cinnarizine usually helps vomiting, and restriction of salt and fluid may hasten resolution. Occasionally diuretics may be used but there is little evidence for efficacy.

Work Smart Session - MRCP Part 1

Question: 30 of 100

A 29-year-old female presents with acute right-sided weakness.

She has one child aged four years and had two spontaneous abortions in the past. After the birth of her child she developed a DVT and required three months' anticoagulation with warfarin.

Examination revealed a right hemiparesis. A CT head scan showed a left middle cerebral artery territory infarct.

What is the most likely finding on echocardiography?

(Please select 1 option)

- Atrial septal defect
- Bicuspid aortic valve
- Left atrial myxoma
- Normal appearances
- Ventricular septal defect

Submit answer | Skip question | Tag Question | Remove question

A 29-year-old female presents with acute right-sided weakness.

She has one child aged four years and had two spontaneous abortions in the past. After the birth of her child she developed a DVT and required three months' anticoagulation with warfarin.

Examination revealed a right hemiparesis. A CT head scan showed a left middle cerebral artery territory infarct.

What is the most likely finding on echocardiography?

(Please select 1 option)

○	Atrial septal defect
○	Bicuspid aortic valve
○	Left atrial myxoma
◉	Normal appearances ✓ Correct
○	Ventricular septal defect

This patient has a prothrombotic tendency suggestive of the lupus anticoagulant with recurrent abortions, previous deep vein thrombosis (DVT) and now she has developed a left hemiparesis.

This has occurred off warfarin and it is highly unlikely to be due to any right to left transference of clot.

It is more likely to be due to spontaneous infarct related to the thrombophilia and her heart is likely to be normal.

Work Smart Session - MRCP Part 1

Question: 31 of 100

A 40-year-old man suffers an intracerebral infarction.

Which of the following features in this patient would not be considered as a risk factor for his stroke?

(Please select 1 option)

- Blood pressure 156/72 mmHg
- Marijuana use
- Mitral valve prolapse
- Plasma cholesterol of 6.5 mmol/l
- Smoker of 5 cigarettes per day

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Question: 31 of 100

A 40-year-old man suffers an intracerebral infarction.

Which of the following features in this patient would not be considered as a risk factor for his stroke?

(Please select 1 option)

○	Blood pressure 156/72 mmHg
◉	Marijuana use ✓ Correct
○	Mitral valve prolapse
○	Plasma cholesterol of 6.5 mmol/l
○	Smoker of 5 cigarettes per day

Like ischaemic heart disease/myocardial infarction (IHD/MI), epidemiological studies show an increased risk of stroke associated with hypercholesterolaemia. Other risk factors for stroke include isolated systolic hypertension in particular.

A previous history of deep vein thrombosis (DVT) may suggest a coagulation disorder.

Cocaine is associated with an increased risk of intracerebral infarction; marijuana is associated with increased susceptibility to schizophrenic episodes, particularly in the younger age group.

A 30-year-old woman complains of daily frontal headaches for the preceding year. They occur at various times of the day and are worse with stress.

On examination, the left pupil is 2 mm larger than the right. It is reactive to accommodation but not to light.

Which of the following features would be inconsistent with the diagnosis?

(Please select 1 option)

○	Absent biceps jerk
◉	Exaggerated response to dilute pilocarpine drops instilled in the left eye ✕ Incorrect answer selected
○	Fine hand tremor
○	Ptosis ← This is the correct answer
○	Resolution of anisocoria with time

This patient has an Adie pupil which happens to coexist with tension headache.

An absent biceps jerk would be consistent with Holmes-Adie syndrome.

The characteristic abnormality in this condition is degeneration of parasympathetic nerves in the cilliary ganglion which leads to denervation of the pupil and hence hypersensitvity to dilute pilocarpine drops. The affected pupil is usually larger than the other but may constrict with time.

The cause of the associated arreflexia is unknown. A fine hand tremor may accompany anxiety states associated with tension headache but ptosis requires an organic explanation.

- Help

○	Is classically due to deficiency of tyrosine hydroxylase
○	Mental retardation does not occur if the patient adheres to a phenylalanine free diet
○	Serum tyrosine levels are typically low
◉	Urinary phenylalanine metabolites are typically high ✓ Correct

Phenylketonuria (PKU) is the result of hyperphenylalaninaemia. It is autosomal recessive, with a prevalence of 1:10-20,000 live births.

Phenylalanine is an essential amino acid. Dietary phenylalanine is not utilised for protein synthesis, but is normally degraded via the tyrosine pathway. Failure of this results in other metabolites that cause brain damage.

Deficiency of phenylalanine hydroxylase (chromosome 12) or of the cofactor tetrahydrobiopterin (genes on chromosome 10 and 4) causes accumulation of phenylalanine in body fluids. The affected infant is usually normal at birth, and although blood phenylalanine levels may rise as early as four hours after birth, mental retardation develops gradually, and may not be apparent for a few months.

About 25% of infants have seizures, but over 50% have an abnormal EEG.

Microcephaly, prominent maxilla, growth retardation and wide-spaced teeth are found in untreated children.

Even with dietary treatment some degree of cognitive impairment is seen, and can vary from gross impairment or changes detected on cognitive tests.

Cerebral white matter changes are seen in older patients and may reflect a combination of late diagnosis and dietary indiscretion.

Diagnosis of classic PKU requires raised Phe levels, normal plasma tyrosine levels, increased urinary Phe metabolites and normal cofactor (tetrahydrobiopterin) concentrations.

Time taken: 1 hrs 48 mins 20 secs

Work Smart Session - MRCP Part 1

Question: 34 of 100

A 40-year-old civil servant attends the clinic stating that she has difficulty swallowing.

She gives a two month history of difficulty with solids which has progressed to difficulty tolerating liquids in the previous two weeks. She has noticed some weakness in her right arm which has affected her ability to lift certain objects like the kettle. Previously, she has enjoyed good health with no hearing loss or facial weakness. She describes no visual symptoms.

On examination, she has an absent gag reflex on the right, with reduced palatal movements. There is weakness on rotating the head to the left with flattening and weakness of elevation of the right shoulder. Eye movements, visual acuity, hearing and tongue movements are all normal.

Where is the likely site of the lesion?

(Please select 1 option)

○	Left cerebello-pontine angle
○	Left jugular foramen
○	Right cerebello-pontine angle
○	Right jugular foramen
○	Right pons

Submit answer | Skip question | Tag Question | Remove question

movements are all normal.

Where is the likely site of the lesion?

(Please select 1 option)

○	Left cerebello-pontine angle
○	Left jugular foramen
○	Right cerebello-pontine angle
◉	Right jugular foramen ✓ Correct
○	Right pons

The clinical scenario is that of a right sided pathology affecting the IX, X and XI cranial nerves.

This produces the palatal weakness and the swallowing difficulties (IX/X), while the shoulder and sternocleidomastoid weakness are due to accessory nerve (XI) involvement.

The absence of hearing loss or facial weakness makes a cerebello-pontine angle lesion unlikely.

A lesion outside the skull may also involve the XII nerve (tongue).

The most likely site, therefore is the jugular foramen.

☆☆☆☆☆

A 60-year-old woman attends the casualty department with a six week history of lethargy, neck pain, weakness in the upper limbs and gait disturbance. She describes occasional episodes of electrical sensation shooting down her spine on flexing her neck.

She has a long history of lower back pain, primary generalised osteoarthritis, and vitiligo. She takes voltarol regularly. She neither smokes nor drinks.

She is of Pakistani origin and has been in this country for the past six years. There is no history of recent foreign travel.

On examination she is afebrile. General examination is unremarkable except for vitiligo. Examination of the cranial nerves is normal. There is no wasting of the limbs but there are a few fasciculations in brachioradialis and biceps on the right. Tone is mildly increased. Apart from mild weakness of elbow, wrist and finger flexion and extension, more marked on the right, power is normal. There is inversion of the right supinator reflex, and triceps, knee and ankle jerks are brisk bilaterally. Right plantar is extensor, the left flexor. Sensation and coordination are within normal limits. Gait is mildly spastic.

Investigations show:

Hb	11.3 g/L (11.5-16.5)
WCC	7 x 10^9/L (4-11 x10^9)
Platelets	130 x 10^9/L (150-400 x10^9)
Coagulation screen	Normal
ESR	27 mm/h (0-30mm/1st hour)
CRP	17 mg/L (<10)
Sodium	137 mmol/l (137-144)
Potassium	4.2 mmol/l (3.5-4.9)
Urea	5.7 mmol/l (2.5-7.5)
Creatinine	87 umol/l (60-110)

CRP	17 mg/L (<10)
Sodium	137 mmol/l (137-144)
Potassium	4.2 mmol/l (3.5-4.9)
Urea	5.7 mmol/l (2.5-7.5)
Creatinine	87 µmol/l (60-110)
Protein	83 g/L (61-76)
Albumin	33 g/L (37-49)
Calcium	2.23 mmol/l (2.2-2.6)
Phosphate	1.2 mmol/l (0.8-1.4)
LFTs	Normal
CXR:	Normal
x Ray cervical spine:	Extensive osteophytes. Normal alignment.

What is the most likely diagnosis?

(Please select 1 option)

- ○ Degenerative cervical spondyloarthropathy
- ○ Motor neurone disease
- ○ Multiple myeloma
- ○ Polymyalgia rheumatica
- ○ Syringomyelia

LFTs	Normal
CXR:	Normal
x Ray cervical spine:	Extensive osteophytes. Normal alignment.

What is the most likely diagnosis?

(Please select 1 option)

○	Degenerative cervical spondyloarthropathy ← This is the correct answer
◉	Motor neurone disease ✕ Incorrect answer selected
○	Multiple myeloma
○	Polymyalgia rheumatica
○	Syringomyelia

The inverted supinator jerk localises the lesion to C 5/6.

Cervical spondylosis is associated with pain in the neck that may radiate down the arms or back. Sphincter disturbance is uncommon.

Multiple myeloma is associated with a high erythrocyte sedimentation rate, renal impairment, hypercalcaemia and raised globulin.

Syringomyelia would involve sensory modalities.

Motor neurone disease is a possibility, although it would be unusual for MND to localise this specifically to the C spine.

Work Smart Session - MRCP Part 1

Question: 36 of 100

A 55-year-old Caucasian man presented to hospital with fever, intermittent rigors, and worsening fatigue. He had returned from a business trip to West Africa six months previously.

What is the most likely diagnosis?

(Please select 1 option)

○	Brucellosis
○	Leishmaniasis
○	*Plasmodium falciparum* malaria
○	*Plasmodium ovale* malaria
○	Typhoid fever

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

○	Brucellosis
○	Leishmaniasis
○	*Plasmodium falciparum* malaria
◉	*Plasmodium ovale* malaria ✓ Correct
○	Typhoid fever

The Duffy blood group on the red blood cells acts as a receptor for *P. vivax*. West Africans lack the Duffy blood group and therefore *P. ovale* replaces *P. vivax* in this region.

Both *P. vivax* and *P. ovale* have a liver hypnozoite stage which can cause repeated relapses.

P. falciparum typically presents within the first three months of return.

Visceral leishmaniasis is not endemic in West Africa.

Brucellosis is a zoonosis transmitted through contaminated and untreated milk and by direct contact with infected animals. The incubation period of brucellosis is usually one to three weeks, but sometimes may be several months. It may have either a sudden or insidious onset and is accompanied by continued, intermittent, or irregular fever.

Typhoid fever presents within one to three weeks from return from an endemic area.

Work Smart Session - MRCP Part 1

Question: 37 of 100

A 30-year-old female was commenced on carbamazepine for partial complex seizures and was also advised to discontinue her moderate alcohol consumption.

Therapeutic concentrations of carbamazepine were achieved within four days with a dose of 200 mg daily but the dose needed to be increased to 400 mg daily within two weeks to achieve a therapeutic plasma concentration.

Which one of the following is likely to account for this observation?

(Please select 1 option)

○	Auto-induction of carbamazepine metabolism
○	Auto-inhibition of carbamazepine metabolism
◉	Cessation of alcohol intake
○	Concomitant prescription of the oral contraceptive pill
○	Reduced bioavailablity of carbamazepine

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Question: 37 of 100

A 30-year-old female was commenced on carbamazepine for partial complex seizures and was also advised to discontinue her moderate alcohol consumption.

Therapeutic concentrations of carbamazepine were achieved within four days with a dose of 200 mg daily but the dose needed to be increased to 400 mg daily within two weeks to achieve a therapeutic plasma concentration.

Which one of the following is likely to account for this observation?

(Please select 1 option)

○	Auto-induction of carbamazepine metabolism ← This is the correct answer
○	Auto-inhibition of carbamazepine metabolism
◉	Cessation of alcohol intake ✕ Incorrect answer selected
○	Concomitant prescription of the oral contraceptive pill
○	Reduced bioavailablity of carbamazepine

Alcohol is a liver enzyme inducer therefore stopping the alcohol should increase the activity of the carbamazepine not reduce its activity.

It is well recognised that carbamazepine is a P450 enzyme inducer but it is less well appreciated that it causes auto-induction and so would require increase in dose to maintain the same therapeutic concentration.

Work Smart Session - MRCP Part 1

Question: 38 of 100

A 50-year-old man presented with paraesthesia in the ring and little fingers of his right hand.

On examination there was wasting of the hypothenar eminence of his right hand.

Which one of the following movements would you expect to be weak in this patient?

(Please select 1 option)

○	Abduction of the thumb
○	Adduction of the thumb
○	Extension of the little finger
○	Flexion of the index finger
○	Opposition of the thumb

Submit answer | Skip question | Tag Question | Remove question

A 50-year-old man presented with paraesthesia in the ring and little fingers of his right hand.

On examination there was wasting of the hypothenar eminence of his right hand.

Which one of the following movements would you expect to be weak in this patient?

(Please select 1 option)

○	Abduction of the thumb
◉	Adduction of the thumb ✓ Correct
○	Extension of the little finger
○	Flexion of the index finger
○	Opposition of the thumb

The clinical features suggest an ulnar neuropathy.

Abduction and opposition of the thumb and flexion of the index finger are via the median nerve.

Extension of the little finger is via the radial nerve.

Work Smart Session - MRCP Part 1

Question: 39 of 100

A 55-year-old man presents with a resting tremor of his right arm and a diagnosis of idiopathic Parkinson's disease is made.

Which one of the following drugs is most likely to help his tremor?

(Please select 1 option)

- Amantadine
- Benzhexol
- Cabergoline
- Co-careldopa
- Selegiline

Submit answer | Skip question | Tag Question | Remove question

Time taken: 2 hrs 57 mins 19 secs

Work Smart Session - MRCP Part 1

Question: 39 of 100

A 55-year-old man presents with a resting tremor of his right arm and a diagnosis of idiopathic Parkinson's disease is made.

Which one of the following drugs is most likely to help his tremor?

(Please select 1 option)

○	Amantadine
◉	Benzhexol ✓ Correct
○	Cabergoline
○	Co-careldopa
○	Selegiline

Anticholinergic treatment (for example, benzhexol) is the treatment of choice of tremor predominantly Parkinson's disease.

L-dopa and dopamine agonists are the treatment of choice for bradykinesia and rigidity.

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 34-year-old male presents with back pain and weakness.

Which of the following would support a diagnosis of prolapsed intervertebral disc?

(Please select 1 option)

○	Bilateral symmetrical nerve involvement
○	Loss of sensation over the left outer upper thigh ← This is the correct answer
○	No evidence of nerve compression
◉	Pain which is unremitting in character ✕ Incorrect answer selected
○	Pain which is worse on resting

Prolapsed intervertebral disc is associated with pain and neurological loss in one nerve root.

Frequently roots of the sciatic nerve are affected.

Compression of more than one root suggests an alternative diagnosis.

Pain at rest would suggest an alternative diagnosis such as infection, tumour or metabolic disease, as would unremitting pain.

Work Smart Session - MRCP Part 1

Question: 4 of 100

A 26-year-old female is admitted to ICU with severe asthma.

She is ventilated for one week, and receives IV co-amoxiclav/clarithromycin, magnesium, prednisolone, sedatives and muscle relaxants.

She improves gradually but two days after stopping muscle relaxants she still is unable to be weaned from ventilatory support.

On examination, she is alert but has flaccid weakness of all limbs.

Which of the following is the likely diagnosis?

(Please select 1 option)

○	Critical illness polyneuropathy
○	Guillain-Barré syndrome
○	Hypermagnesaemia
○	Prolonged neuromuscular blockade
○	Steroid induced myopathy

Work Smart Session - MRCP Part 1

Question: 40 of 100

A 39-year-old painter presents with a burning pain in both feet, which has deteriorated over the last six months.

He drinks 60 units of alcohol weekly and has a family history of pernicious anaemia.

On examination he has impairment of all modalities of sensation in both feet but particularly pain and temperature and absent ankle jerks.

What is the most likely diagnosis?

(Please select 1 option)

○	Alcoholic peripheral neuropathy
○	Chronic inflammatory demyelinating polyradiculopathy
○	Hereditary sensory neuropathy
○	Lead neuropathy
○	Vitamin B12 deficiency

Submit answer | Skip question | Tag Question | Remove question

He drinks 60 units of alcohol weekly and has a family history of pernicious anaemia.

On examination he has impairment of all modalities of sensation in both feet but particularly pain and temperature and absent ankle jerks.

What is the most likely diagnosis?

(Please select 1 option)

◉	Alcoholic peripheral neuropathy ✓ Correct
○	Chronic inflammatory demyelinating polyradiculopathy
○	Hereditary sensory neuropathy
○	Lead neuropathy
○	Vitamin B12 deficiency

Alcohol abuse and diabetes are the commonest causes of peripheral neuropathy in the United Kingdom.

Vitamin B12 deficiency causes neuropathy that affects only the dorsal column (joint position, light touch and vibration).

Lead neuropathy is purely motor affecting mainly the upper limbs.

Chronic inflammatory demyelinating polyradiculopathy causes manly motor impairment (distal and proximal).

Time taken: 2 hrs 59 mins 44 secs

Work Smart Session - MRCP Part 1

Question: 41 of 100

A 35-year-old woman presents with pains in the right arm.

On examination she has wasting and weakness of the intrinsic muscles of the right hand, absent tendon reflexes in the right arm and impaired pinprick sensation in the right hand and forearm.

What is the most likely diagnosis?

(Please select 1 option)

- Combined median and ulnar nerve lesions
- Lower trunk brachial plexus lesion
- Neuralgic amyotrophy
- Syringomyelia
- Thoracic outlet syndrome

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 35-year-old woman presents with pains in the right arm.

On examination she has wasting and weakness of the intrinsic muscles of the right hand, absent tendon reflexes in the right arm and impaired pinprick sensation in the right hand and forearm.

What is the most likely diagnosis?

(Please select 1 option)

○	Combined median and ulnar nerve lesions
○	Lower trunk brachial plexus lesion
○	Neuralgic amyotrophy
◉	Syringomyelia ✓ Correct
○	Thoracic outlet syndrome

Median and ulnar nerve lesions would not cause absent reflexes in the arm.

Lower trunk brachial plexus (C8/T1) would not cause absent reflexes in the arm.

Neuralgic amyotrophy affects the upper plexus (C5-6) and therefore does not cause wasting of small muscles of hand.

Thoracic outlet syndrome will not cause absent reflexes.

Syringomyelia typically causes loss of reflexes, spinothalamic sensory loss, and weakness. It can be asymmetrical initially.

Work Smart Session - MRCP Part 1

Question: 42 of 100

A 30-year-old female presents with weight gain, some hair loss and a tremor six months after commencing single drug treatment.

Which one of the following drugs is most likely to be responsible for her symptoms?

(Please select 1 option)

○	Carbamazepine
○	Lamotrigine
○	Phenytoin
○	Sodium valproate
◉	Topiramate

Submit answer | Skip question | Tag Question | Remove question

○	Lamotrigine
○	Phenytoin
◉	Sodium valproate ✓ Correct
○	Topiramate

Sodium valproate is associated with

- weight gain
- tremor
- hair loss
- teratogenicity
- polycystic ovary disease.

Lamotrigine is associated with skin rash (and Stevens-Johnson syndrome in severe cases).

Topiramate is associated with

- renal stones
- weight loss
- cognitive impairment
- tingling in extremities.

Phenytoin is associated with

- peripheral neuropathy
- cerebellum syndrome
- acne
- hirsutism
- gingival hypertrophy
- hypocalcaemia.

Time taken: 3 hrs 2 mins 38 secs

Work Smart Session - MRCP Part 1

Question: 43 of 100

A 30-year-old man complains of fairly rapid worsening of his central vision. His acuity is normal on pinhole testing.

Which of the following would not account for his symptoms?

(Please select 1 option)

- Diabetes mellitus
- Eye drops
- Eyelid swelling
- Lens subluxation
- Open angle glaucoma

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which of the following would not account for his symptoms?

(Please select 1 option)

○	Diabetes mellitus
○	Eye drops
◉	Eyelid swelling ✗ Incorrect answer selected
○	Lens subluxation
○	Open angle glaucoma ← This is the correct answer

The defect in this patient's vision is corrected by viewing through a pinhole, which means that the problem is refractive and must therefore be localised to the cornea or the lens.

Causes of rapid changes in refractive error include:

- Senile cataract (increasingly myopic)
- Diabetes mellitus (high glucose raises refractive index of lens, hence myopic)
- Keratoconus (conical cornea, may occur rapidly in adolescence or early adulthood and causes myopia and astigmatism)
- Subluxation of the lens
- Eye drops (miotics produce myopia, mydriatics lead to hypermetropia) and
- Eyelid swelling.

Open angle glaucoma is associated with damage to the ganglion cells of the retina and therefore any visual deficit that is produced by it will not correct with a pinhole.

Work Smart Session - MRCP Part 1

Question: 44 of 100

Which of the following statements regarding CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is correct?

(Please select 1 option)

- ○ It is associated with an abnormality of the X chromosome
- ○ It may present with migraine
- ◉ Computerised tomography (CT) of the brain is diagnostic
- ○ Death usually occurs in infancy
- ○ The thalami are usually spared

Submit answer | Skip question | Tag Question | Remove question

- Shop
- Help

(Please select 1 option)

○	It is associated with an abnormality of the X chromosome
◉	It may present with migraine ✓ Correct
○	Computerised tomography (CT) of the brain is diagnostic
○	Death usually occurs in infancy
○	The thalami are usually spared

CADASIL is a diffuse disease of small arteries, predominantly in the brain.

- It starts during mid adulthood and is characterised by:
-
- recurrent ischaemic events (transient or permanent)
- attacks of migraine with aura
- severe mood disorders
- sub-cortical dementia and
- a wide spread leukoencephalopathy on magnetic resonance imaging (MRI).
-
- CT brain is not diagnostic. Characteristic MRI changes include T2 .weighted hyperintensity of the periventricular white matter.
-
- A family history is almost always present, as it is an autosomal dominant condition, located to chromosome 19.
-
- Infarcts are subcortical, and the thalami and basal ganglia are usually involved.

Time taken: 3 hrs 5 mins 35 secs

Work Smart Session - MRCP Part 1

Question: 45 of 100

A 28-year-old shop worker is referred with a three month history of recurrent episodes of disorientation and confusion.

Her boyfriend has found her wandering around the house on several occasions, apparently with no idea of where she is or how she got there. Her mood has been very low, with frequent emotional outbursts, and she has considered leaving her job because of problems with working the computer and managing customer's queries. Her boyfriend feels her condition is significantly worsening.

Physical examination is normal, apart from recurrent, asymetrical, jerks in all four limbs.

Which of the following investigations is likely to be most useful in reaching a diagnosis?

(Please select 1 option)

○	Chest x ray
○	CT head
○	EEG
○	Liver function tests
○	Visual evoked potentials

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which of the following investigations is likely to be most useful in reaching a diagnosis?

(Please select 1 option)

○	Chest x ray
○	CT head
◉	EEG ✓ Correct
○	Liver function tests
○	Visual evoked potentials

This kind of rapid cognitive decline in a young person with myoclonus is strongly suggestive of Creutzfeldt-Jakob disease (CJD). This may be new variant (in which the electroencephalogram [EEG] may be abnormal though is often normal) or sporadic in which case characteristic EEG abnormalities may be expected.

The EEG in sporadic CJD may show significant abnormalities involving deep brain areas such as the thalami. Initially the changes are diffuse, and non-specific, developing into stereotyped high voltage components on a slow background. High voltage sharp waves may be synchronous with myoclonic jerks.

Tonsillar biopsy for 14-3-3 protein marker has a diagnostic sensitivity of around 80% for prion proteins.

Other investigations to exclude other causes of rapid cognitive decline, would include magnetic resonance imaging (MRI) and lumbar puncture.

Computed tomography (CT) may show non-specific changes with atrophy out of keeping with the patient's age.

Diagnosis is confirmed with biopsy.

- Help

Which of the following would be most useful in the diagnosis of his condition?

(Please select 1 option)

◉	Anti-Purkinje cell antibody levels ✓ Correct
○	Lumbar puncture
○	Serum calcium
○	Serum sodium
○	Visual evoked potentials

Paraneoplastic syndromes are a result of antibody generation from or against malignant cells attacking normal tissue.

Examples include antineuronal antibodies (anti-Hu, anti-Yo, anti-Ri) directed against the Purkinje cells of the cerebellum leading to the cerebellar syndrome described above.

The Lambert-Eaton myasthenic syndrome (LEMS) is a pre-synaptic disorder of auto-antibody IgG directed against the pre-synaptic calcium channel leading to impaired acetylcholine release. Clinically, patients present with muscle weakness that improves with exercise.

Symptomatic hyponatraemia due to syndrome of inappropriate antidiuretic hormone secretion (SIADH) is treated with demeclocycline which induces nephrogenic diabetes insipidus leading to excretion of excess water.

Both non-small cell and small cell lung cancers are associated with paraneoplastic syndromes, although they are more common with the latter due to its neuroendocrine cell origin.

Question: 47 of 100

A 39-year-old woman is found to have absent ankle jerks and gait disturbance.

Which of the following investigations is not indicated?

(Please select 1 option)

- ANA
- B_{12} levels
- Cholestanol levels
- Ferritin
- VDRL

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

- Help

○	ANA
○	B_{12} levels
○	Cholestanol levels
◉	Ferritin ✓ Correct
○	VDRL

Absent ankle jerks may occur in conditions associated with neuropathy (B_{12} deficiency, SLE, cerebrotendinous xanthomatosis) and dorsal root disease (tabes dorsalis).

Gait disturbance may occur for a variety of reasons:

- Sensory ataxia in B_{12} deficiency and tabes dorsalis
- Pyramidal signs in B_{12} deficiency and SLE
- Cerebellar ataxia in cerebrotendinous xanthomatosis.

Cerebrotendinous xanthomatosis is an inherited condition, associated with accumulation of cholesterol in tissues including brain, peripheral nerve and tendons which produces a clinical picture of

- early onset dementia
- gait ataxia
- loss of vibration sense
- cataracts
- large tendon xanthomata.

It is eminently treatable by the oral administration of chenodeoxycholic acid.

Work Smart Session - MRCP Part 1

Question: 48 of 100

A male teacher who is 31-years-old attends clinic with his partner who tells you that he has memory problems. The only other symptom is intermittent diarrhoea over the preceding four months.

He has limited vertical eye movements and exhibits rhythmic simultaneous eye and mouth movements.

Which pathogen is most likely to be the cause of his symptoms?

(Please select 1 option)

○	*Clostridium botulinum*
○	HIV
○	Prion protein
○	*Salmonella enteritidis*
○	*Tropheryma whippleii*

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	HIV
◉	Prion protein ✗ Incorrect answer selected
○	*Salmonella enteritidis*
○	*Tropheryma whippleii* ← This is the correct answer

This is a tough question.

The suggestion here is that the patient has Whipple's disease, due to intestinal infection with *Tropheryma whipplei*.

Non-neurological manifestations of Whipple's disease are more common and include chronic diarrhoea, malabsorption with steatorrhoea and associated abdominal distension and tenderness.

Neurological manifestations involve a chronic progressive impairment of higher mental function in association with seizures, myoclonus ataxia and oculomasticatory myorhythmia found uniquely in Whipple's.

The diagnosis is made by duodenal or jejunal biopsy and demonstrating the bacilli within the mucosa on PAS staining.

Characteristically, there is accumulation of glycoprotein and fat filled (PAS +ve) macrophage within the lamina propria.

Botulism does not produce this clinical picture.

An AIDS related dementia is possible, but abnormal facial movements would be unusual.

Creutzfeldt-Jakob disease (CJD) could also produce this picture, although myoclonus is usually more of a feature and cognitive impairment is more generalised and acute.

Salmonella enteritidis usually causes only an acute diarrhoeal illness, but may lead to bacteraemia and chronic long-term carriage and excretion.

Question: 49 of 100

An 18-year-old male is diagnosed with Becker's muscular dystrophy.

Which of the following statements concerning the genetics of the condition is correct?

(Please select 1 option)

○	His brothers will all be affected
○	His daughters will have a 50% chance of being carriers
◉	His daughters' sons will have a 50% chance of having the disease ✓ Correct
○	His sons will be carriers of the condition
○	His sons' children will have a 50% chance of having the disease

Becker's muscular dystrophy is an X-linked condition and so 50% of males will be affected in a family.

His sons will get the X chromosome from his wife and so will not be carriers but all his daughters will be carriers.

However, his daughters' sons will consequently have a 50% chance of inheriting the disease as all his daughters are carriers and there is a one in two chance (50:50) of passing the gene onto their sons.

On the other hand his sons who are not affected do not pass on the condition.

☆☆☆☆☆

relaxants.

She improves gradually but two days after stopping muscle relaxants she still is unable to be weaned from ventilatory support.

On examination, she is alert but has flaccid weakness of all limbs.

Which of the following is the likely diagnosis?

(Please select 1 option)

○	Critical illness polyneuropathy
○	Guillain-Barré syndrome
○	Hypermagnesaemia
◉	Prolonged neuromuscular blockade ✓ Correct
○	Steroid induced myopathy

The history suggests prolonged neuromuscular junction (NMJ) blockade which may be exacerbated by both corticosteroids and magnesium.

This condition was originally described with suxamethonium due to hereditary reductions in plasma cholinesterase activity. However, drugs and electrolyte abnormalities may exacerbate this.

Question: 50 of 100

A 43-year-old man presented with diplopia of six weeks duration. On examination he had normal corrected visual acuity in each eye, restriction of adduction of the right eye and nystagmus in the left eye on left lateral gaze.

What is the most likely diagnosis?

(Please select 1 option)

○	Brainstem demyelination ← This is the correct answer
○	Graves' ophthalmopathy
○	Internal carotid artery aneurysm
○	Lateral medullary syndrome
◉	Steele-Richardson syndrome ✕ Incorrect answer selected

The features are suggestive of internuclear ophthalmoplegia which is due to a lesion at the medial longitudinal fasciculus and in this male the most likely explanation is multiple sclerosis (MS).

Other causes include brainstem infarction, syphilis and Lyme disease.

Work Smart Session - MRCP Part 1

Question: 51 of 100

Which vertebral level and corresponding structure is correct?

(Please select 1 option)

○	C4 and bifurcation of the carotid artery
○	T2 and manubriosternal joint
○	T8 and aortic opening in the diaphragm
○	T10 and opening for vena cava in diaphragm
○	T12 and oesophageal opening in the diaphragm

Submit answer | Skip question | Tag Question | Remove question

Time taken: 3 hrs 19 mins 5 secs

Work Smart Session - MRCP Part 1

Question: 51 of 100

Which vertebral level and corresponding structure is correct?

(Please select 1 option)

◉	C4 and bifurcation of the carotid artery ✓ Correct
○	T2 and manubriosternal joint
○	T8 and aortic opening in the diaphragm
○	T10 and opening for vena cava in diaphragm
○	T12 and oesophageal opening in the diaphragm

The carotid artery bifurcates at C4.

The manubriosternsal joint (angle of Louis) lies at the level of the T4/5 intervertebral disk.

The caval opening in the diaphragm lies at T8.

The oesoghageal opening of the diaphragm lies at T10.

The aortic opening is at T12.

Question: 52 of 100

An 18-year-old woman sustains severe head injuries in a road traffic accident.

The following day her investigations show:

Sodium	160 mmol/l	(137-144)
Potassium	3.7 mmol/l	(3.5-4.9)
Chloride	120 mmol/l	(95-107)
Urea	3.0 mmol/l	(2.5-7.5)
Creatinine	90 µmol/l	(60- 110)

Which one of the following statements is correct?

(Please select 1 option)

- Rapid rehydration with 5% dextrose is indicated
- She has the syndrome of inappropriate antidiuretic hormone secretion (SIADH)
- She should be treated with sodium restriction
- She will have a hypercholraemic acidosis
- Urine osmolality will be low

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Chloride	120 mmol/l	(95-107)
Urea	3.0 mmol/l	(2.5-7.5)
Creatinine	90 µmol/l	(60- 110)

Which one of the following statements is correct?

(Please select 1 option)

○	Rapid rehydration with 5% dextrose is indicated
○	She has the syndrome of inappropriate antidiuretic hormone secretion (SIADH)
◉	She should be treated with sodium restriction ✕ Incorrect answer selected
○	She will have a hypercholraemic acidosis
○	Urine osmolality will be low ← This is the correct answer

There is a marked hypernatraemia with elevated chloride but normal potassium and urea in a patient with severe head injuries.

The likely cause of this presentation is diabetes insipidus. Urine osmolality is therefore likely to be low.

You cannot say that she has a hyperchloraemic acidosis as you do not have her bicarbonate concentration but if you assume that the anion gap would be normal, that is 10-12, then this would suggest that the bicarbonate is elevated, suggesting either a metabolic alkalosis or respiratory acidosis with compensation.

Although restoration of normal volaemia and osmolality is required, giving 5% dextrose may exacerbate any cerebral oedema and so correction should be gradual.

Time taken: 3 hrs 33 mins 9 secs

Work Smart Session - MRCP Part 1

Question: 53 of 100

An 80-year-old male presented with acute right-sided weakness.

Examination revealed minimal right facial weakness, impaired elevation of the right shoulder, with relatively preserved right hand strength. There was global weakness in the right leg which appeared to be maximal in the foot.

Which of the following arteries is most likely to have been affected?

(Please select 1 option)

- Anterior cerebral artery
- Lenticulostriate artery
- Middle cerebral artery
- Posterior cerebral artery
- Posterior communicating artery

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Anterior cerebral artery ← This is the correct answer
○	Lenticulostriate artery
◉	Middle cerebral artery ✕ Incorrect answer selected
○	Posterior cerebral artery
○	Posterior communicating artery

It's a tricky question and it is purposely so.

The wording of the description could be due to middle or anterior artery circulation stroke but the challenge is to choose which is the more likely.

The case as described is the classic presentation of an anterior cerebral artery stroke as originally described in the literature. (Critchley M. The anterior cerebral artery and its syndromes. Brain 1930; 53:120-165.)

Unilateral occlusion (distal to ant. comm. origin) of **anterior cerebral artery** produces contralateral sensorimotor deficits mainly involving the lower extremity with relative sparing of face and hands (think of the humunculus).

The lateral lenticulostriate artery is a branch of the middle cerebral artery. Occlusion causes damage to the internal capsule resulting in contralateral hemiparesis and sensory deficit. Speech may be affected (medial temporal lobe) as well as visual function (Meyer's loop: optic radiations affected).

Middle cerebral artery: Occlusion at the stem (proximal segment) results in:

- Contralateral hemiplegia affecting face, arm, and leg (lesser)
- Homonymous hemianopia - ipsilateral head/eye deviation
- If on left: global aphasia

Posterior cerebral artery: A variety of neurological syndromes including:

- Pure hemisensory loss
- Visual field loss- a variety
- Visual agnosia
- Disorders of reading (alexia, dyslexia) and more ...

Work Smart Session - MRCP Part 1

Question: 54 of 100

A 60-year-old woman presented with a small right pupil, right ptosis and impaired sweating over the ipsilateral forehead. Sweating on the rest of the face was unaffected.

Where is the most likely site of this lesion?

(Please select 1 option)

- Cervical spinal cord
- Common carotid artery
- Hypothalamus
- Internal carotid artery
- Lateral medulla

Submit answer | Skip question | Tag Question | Remove question

Time taken: 3 hrs 39 mins 14 secs

Work Smart Session - MRCP Part 1

Question: 54 of 100

A 60-year-old woman presented with a small right pupil, right ptosis and impaired sweating over the ipsilateral forehead. Sweating on the rest of the face was unaffected.

Where is the most likely site of this lesion?

(Please select 1 option)

○	Cervical spinal cord
○	Common carotid artery
○	Hypothalamus
◉	Internal carotid artery ✓ Correct
○	Lateral medulla

Because the sympathetic plexus accompanying the internal carotid artery innervates sweat glands only to the medial forehead, facial anhydrosis does not occur significantly with postganglionic Horner syndrome.

Work Smart Session - MRCP Part 1

Question: 55 of 100

A 56-year-old woman presents with problematical tremor which has deteriorated over the last three months and she notes that it is exacerbated by changes in position.

She has a past history of asthma for which she is taking inhaled salbutamol and one year ago she underwent liver transplantation for primary biliary cirrhosis for which she takes cyclosporin.

On examination she seems quite well but has a noticeable coarse tremor of her outstretched hands. There are no other abnormalities noticeable on neurological examination.

How should this patient be managed?

(Please select 1 option)

○	Add benzhexol
○	L-Dopa
○	Propranolol
◉	Reduce dose cyclosporin
○	Reduce dose salbutamol

Submit answer | Skip question | Tag Question | Remove question

- Help

primary biliary cirrhosis for which she takes cyclosporin.

On examination she seems quite well but has a noticeable coarse tremor of her outstretched hands. There are no other abnormalities noticeable on neurological examination.

How should this patient be managed?

(Please select 1 option)

○	Add benzhexol
○	L-Dopa
○	Propranolol
◉	Reduce dose cyclosporin ✓ Correct
○	Reduce dose salbutamol

Cyclosporin is well known to cause coarse tremor. In the first instance the dose should be reduced. Usually the neurological side effects of cyclosporin are dose dependent.

The tremor with salbutamol tends not to be coarse as described in this case, being approximately 10-12 Hz.

Question: 56 of 100

A 56-year-old female presented to her GP with pain in the left side of her neck radiating down the lateral aspect of her arm and forearm.

She had also noticed some weakness of her left shoulder and struggled to elevate her arm. She had a longstanding history of rheumatoid arthritis, treated with steroids and penicillamine. She was a non-smoker and did not drink any alcohol.

On examination there was some wasting over the left deltoid and evidence of fasciculations. Neck movements appeared full except that lateral movement exacerbated the left arm pain.

On examination of the upper limb, tone appeared reduced at the elbow and wrist and the biceps jerk was only present on re-enforcement. The left supinator jerk was inverted and the triceps jerk appeared brisk. There was some weakness of left shoulder abduction, elbow flexion and supination, but finger movements and elbow extension were intact. There was a sensory deficit over the lateral aspect of the left upper arm and forearm. The right arm appeared normal.

On examination of he lower limb, tone was increased, but power appeared normal. All reflexes were brisk and both plantar responses were extensor.

Investigations showed:

Haemoglobin	11.4 g/dl	(13.0 18.0 g/dL)
White cell count	3.4 x 10^9/L	(4 11 x 10^9/L)
Platelets	245 x 10^9/L	(150 400 x 10^9/L)
ESR (Westergren)	45 mm/1st hour	(0 15 mm/1st hour)
Serum sodium	145 mmol/L	(137 144 mmol/L)
Serum potassium	3.2 mmol/L	(3.5 4.9 mmol/L)
Serum urea	6.7 mmol/L	(2.5 7.5 mmol/L)
Serum creatinine	135 umol/L	(60 110 umol/L)
Serum creatine kinase	178 U/L	(24 170 U/L)
Fasting plasma glucose	8.7 mmol/L	(3 6 mmol/L)

What is the most likely diagnosis?

normal.

On examination of he lower limb, tone was increased, but power appeared normal. All reflexes were brisk and both plantar responses were extensor.

Investigations showed:

Haemoglobin	11.4 g/dl	(13.0 18.0 g/dL)
White cell count	3.4 x 10^9/L	(4 11 x 10^9/L)

Serum creatine kinase	178 U/L	(24 170 U/L)
Fasting plasma glucose	8.7 mmol/L	(3 6 mmol/L)

What is the most likely diagnosis?

(Please select 1 option)

- Cervical myelopathy
- Circumflex neuropathy
- Inclusion body myositis
- Motor neurone disease
- Steroid-induced myopathy

Submit answer | Skip question | Tag Question | Remove question

Serum creatinine	135 umol/L	(60 110 umol/L)
Serum creatine kinase	178 U/L	(24 170 U/L)
Fasting plasma glucose	8.7 mmol/L	(3 6 mmol/L)

What is the most likely diagnosis?

(Please select 1 option)

○	Cervical myelopathy ← This is the correct answer
○	Circumflex neuropathy
◉	Inclusion body myositis ✕ Incorrect answer selected
○	Motor neurone disease
○	Steroid-induced myopathy

This patient has a cervical myelopathy, most likely as a result of her rheumatoid arthritis.

The likely level is C5/C6 given that there is weakness of the deltoid, biceps and supinator and the supinator jerk is inverted.

She also has long tract signs in her legs with hypertonia and hyper-reflexia.

A circumflex neuropathy would account for the weakness and fasciculations of the deltoid, but would not explain the upper motor neurone signs in the legs, or weakness of the biceps and supinator.

Inclusion body myositis, an inflammatory myopathy, would present with bilateral often-asymmetrical weakness, which has a tendency to affect distal musculature. The tendon reflexes would be normal and the creatine kinase would be normal or mildly elevated.

Motor neurone disease presents with upper and lower motor signs in absence of sensory disturbance.

A steroid induced myopathy would cause proximal weakness and wasting with normal reflexes and sensation.

Work Smart Session - MRCP Part 1

Question: 57 of 100

An 80-year-old woman has a three month history of progressive numbness and unsteadiness of her gait.

On examination, there is a mild spastic paraparesis, with brisk knee reflexes, ankle reflexes are present with reinforcement, extensor plantars, sensory loss in the legs with a sensory level at T10, impaired joint position sense in the toes, and loss of vibration sense below the iliac crests.

Investigations were as follows:-

Haemoglobin	12.2 g/dL (12-16)
MCV	95 fL (80-96)

What is the most likely diagnosis?

(Please select 1 option)

- Anterior spinal artery occlusion
- Dorsal meningioma
- Multiple sclerosis
- Subacute combined degeneration of the cord
- Tabes dorsalis

Submit answer | Skip question | Remove Tag | Remove question

Investigations were as follows:-

Haemoglobin	12.2 g/dL (12-16)
MCV	95 fL (80-96)

What is the most likely diagnosis?

(Please select 1 option)

○	Anterior spinal artery occlusion
◉	Dorsal meningioma ✓ Correct
○	Multiple sclerosis
○	Subacute combined degeneration of the cord
○	Tabes dorsalis

The presence of a sensory loss at T10 indicates a thoracic myelopathy.

Subacute combined degeneration of the cord is unlikely as the haemoglobin concentration and mean corpuscular volume (MCV) are normal.

Anterior spinal artery occlusion is unlikely as the history is progessive and chronic.

A 73-year-old man presents with an abrupt onset of double vision and left leg weakness.

Examination shows weakness of abduction of the right eye and right-sided facial weakness affecting upper and lower parts of the face. He also has a left hemiparesis.

Where is the lesion?

(Please select 1 option)

○	Left frontal lobe
○	Left lateral medulla
○	Right corpus striatum
○	Right midbrain
◉	Right pons ✓ Correct

The abducens nucleus is next to the facial nucleus in pons.

They commonly co-exist in a pontine cerebrovascular accident (CVA).

Hemiparesis is also a common feature of pontine lesion.

Question: 59 of 100

A 92-year-old man was admitted in a confused state. He has a history of immobility due to severe lower back pain. He had been losing weight for three months and had complaints of weakness, urinary frequency, thirst, poor urinary stream and constipation.

Lumbar spine x rays show severe osteopenia and collapse of the body of the vertebra at L3. Investigations show:

Haemoglobin	9.6 g/dl	(13.0-18.0)
Sodium	144 mmol/l	(137-144)
Potassium	3.9 mmol/l	(3.5-4.9)
Urea	10.4 mmol/l	(2.5-7.5)
Creatinine	120 mol/l	(60-110)
Glucose	8 mmol/l	(3.0-6.0)
Dipstick urine	Blood ++, protein +	

What is the most important immediate investigation?

(Please select 1 option)

- ○ Chest x ray
- ○ Monosodium urate (MSU)
- ○ Prostate specific antigen
- ○ Serum calcium
- ○ Serum protein electrophoresis

Lumbar spine x rays show severe osteopenia and collapse of the body of the vertebra at L3. Investigations show:

Haemoglobin	9.6 g/dl	(13.0-18.0)
Sodium	144 mmol/l	(137-144)
Potassium	3.9 mmol/l	(3.5-4.9)
Urea	10.4 mmol/l	(2.5-7.5)
Creatinine	120 mol/l	(60-110)
Glucose	8 mmol/l	(3.0-6.0)
Dipstick urine	Blood ++, protein +	

What is the most important immediate investigation?

(Please select 1 option)

○	Chest x ray
○	Monosodium urate (MSU)
○	Prostate specific antigen
○	Serum calcium ← This is the correct answer
◉	Serum protein electrophoresis ✕ Incorrect answer selected

The likely underlying diagnosis is myeloma. The symptoms of constipation, weakness and thirst indicate hypercalcemia.

Serum calcium should be the **immediate** investigation.

pituitary gland.

Which of the following is the likely diagnosis?

(Please select 1 option)

○	Cushing's syndrome
○	Hypothyroidism ← This is the correct answer
◉	Macroprolactinoma ✕ Incorrect answer selected
○	Microprolactinoma
○	Type 2 diabetes

Hypothyroidism is not an uncommon cause of hyperprolactinaemia and should be part of the work up of all patients with an elevated prolactin.

The clinical scenario here would be consistent with a diagnosis of hypothyroidism.

Macroprolactin may masquerade as hyperprolactinaemia and most laboratories now carry out this assay if requested in patients with hyperprolactinaemia. Cabergoline or bromocriptine should only be commenced if a macroprolactinoma is confirmed.

A bulky pituitary gland on CT scan is not a significant finding and an MRI of the pituitary is required to delineate the anatomy of the pituitary gland.

Bitemporal hemianopia would be a feature of a macroprolactinoma impinging on the optic chiasm.

Question: 6 of 100

A 30-year-old lady who suffers from migraine complains that taking the recommended dose of paracetamol during an attack fails to relieve her headache. She has no other significant past medical history. She is a smoker of 15 cigarettes per day and also drinks alcohol 16 units per week.

Which of the following factors most likely explains the lack of efficacy of paracetamol in this lady?

(Please select 1 option)

- Bacterial overgrowth
- Delayed gastric emptying
- First pass metabolism
- p450 enzyme induction
- p450 enzyme inhibition

Work Smart Session - MRCP Part 1

Question: 61 of 100

A 45-year-old man has a history of progressive weakness for five weeks. He had particular difficulty getting out of the bath.

On examination there was severe truncal and proximal limb weakness, without wasting or fasciculation.

Tendon reflexes, plantar responses and sensation were all normal.

The vital capacity was 1.8L.

What is the most likely diagnosis?

(Please select 1 option)

○	Cervical myelitis
○	Guillain-Barre syndrome
○	Polio
○	Polymyositis
○	Syringobulbia

Submit answer | Skip question | Tag Question | Remove question

A 45-year-old man has a history of progressive weakness for five weeks. He had particular difficulty getting out of the bath.

On examination there was severe truncal and proximal limb weakness, without wasting or fasciculation.

Tendon reflexes, plantar responses and sensation were all normal.

The vital capacity was 1.8L.

What is the most likely diagnosis?

(Please select 1 option)

○	Cervical myelitis
◉	Guillain-Barre syndrome ✕ Incorrect answer selected
○	Polio
○	Polymyositis ← This is the correct answer
○	Syringobulbia

The presentation of myopathy is characterised by proximal weakness with normal reflexes and sensation and the absence of fasciculations.

Polymyositis is the commonest cause of inflammatory muscle disease in people under 50-years-old (inclusion body myositis is the commonest in those over 50-years-old).

Work Smart Session - MRCP Part 1

Question: 62 of 100

A 72-year-old woman has a five year history of worsening mental functioning with trouble remembering things. She has no problems with movement.

She is noted on an MRI scan of the brain to have symmetrically increased size of the lateral ventricles along with cerebral cortical atrophy in a mainly frontal and parietal distribution.

A lumbar puncture reveals a normal opening pressure, and analysis of the clear, colorless cerebrospinal fluid reveals glucose and protein which are in normal ranges.

Cell count on the CSF shows 3 WBCs (all lymphocytes) and 1 RBC.

A fundoscopic examination is normal.

Which of the following findings is most likely associated with her underlying disease process?

(Please select 1 option)

○	Increased numbers of Lewy bodies
○	Loss of Betz cells
○	Loss of gamma aminobutyric acid (GABA)
○	Perivascular mononuclear inflammation
○	Presence of the e4 allele of apolipoprotein E

Submit answer | Skip question | Remove Tag | Remove question

She is noted on an MRI scan of the brain to have symmetrically increased size of the lateral ventricles along with cerebral cortical atrophy in a mainly frontal and parietal distribution.

A lumbar puncture reveals a normal opening pressure, and analysis of the clear, colorless cerebrospinal fluid reveals glucose and protein which are in normal ranges.

○	Loss of Betz cells
○	Loss of gamma aminobutyric acid (GABA)
◉	Perivascular mononuclear inflammation ✕ Incorrect answer selected
○	Presence of the e4 allele of apolipoprotein E ← This is the correct answer

She has findings characteristic for Alzheimer's disease.

Loss of GABA is seen in Parkinson's disease.

Perivascular mononuclear inflammation is seen in multiple sclerosis.

Loss of Betz cells is seen in motor neurone disease.

Question: 63 of 100

Which of the following is correct regarding herpes simplex encephalitis?

(Please select 1 option)

○	Is associated with a polymorphonuclear pleocytosis in the CSF
○	Produces a diffuse, evenly distributed inflammation of cerebral tissues
◉	Produces a typical EEG pattern with lateralised periodic discharges at 2 Hz ✓ Correct
○	Should be treated with acyclovir as soon as the diagnosis is confirmed by urgent CSF viral antibody titres
○	Shows a peak incidence in the autumn

This EEG pattern is seen but is not diagnostic.

Winter is the peak incidence.

A lymphocytosis is characteristic in the cerebrospinal fluid (CSF).

Temporal lobe location is typical not diffuse.

Immediate treatment is required on clinical suspicion - do not wait!

Work Smart Session - MRCP Part 1

Question: 64 of 100

A 48-year-old female patient develops an acute, severe and isolated right C6 radiculopathy affecting both the motor and sensory roots.

She is examined in an EMG clinic three weeks after the onset of symptoms.

Which of the following statements is true?

(Please select 1 option)

○	Absent sensory nerve potentials would be expected on examination of the thumb and index finger on the right.
○	A repeat examination 12 months later is likely to reveal rapidly recruited low amplitude short duration motor units in the clinically involved muscle on EMG.
○	Fibrillation potentials would be expected in the right extensor carpi ulnaris and extensor pollicis brevis.
○	Triceps tendon jerk is likely to be depressed or absent.
○	Voluntary motor unit activity may be absent in the right biceps.

Work Smart Session - MRCP Part 1

Question: 64 of 100

A 48-year-old female patient develops an acute, severe and isolated right C6 radiculopathy affecting both the motor and sensory roots.

She is examined in an EMG clinic three weeks after the onset of symptoms.

Which of the following statements is true?

(Please select 1 option)

○	Absent sensory nerve potentials would be expected on examination of the thumb and index finger on the right. ← This is the correct answer
○	A repeat examination 12 months later is likely to reveal rapidly recruited low amplitude short duration motor units in the clinically involved muscle on EMG.
○	Fibrillation potentials would be expected in the right extensor carpi ulnaris and extensor pollicis brevis.
◉	Triceps tendon jerk is likely to be depressed or absent. ✕ Incorrect answer selected
○	Voluntary motor unit activity may be absent in the right biceps.

A difficult question. Thumb and index finger are within the C6 dermatome.

Extensor pollicis brevis and extensor carpi ulnaris are supplied by C7/8. Fibres from C7/8 are also responsible for the triceps reflex.

A pattern of rapidly recruited low amplitude short duration motor units on the electromyogram (EMG) would be considered to represent myopathic changes rather than de-innervation.

Which of the following statements regarding hiccup is true?

(Please select 1 option)

○	Is caused by a tonic relaxation of the diaphragm.
○	Is commonly caused by local irritation to the vagus nerve.
○	Can reliably be treated with theophylline.
○	May be caused by a foreign body in the nose.
◉	May be caused by a posterior fossa tumour. ✓ Correct

Hiccup is caused by frequent or rhythmic clonic contraction of the diaphragm. When prolonged, other causes should be considered including:

- CNS disease: Posterior fossa tumour, brain injury, encephalitis
- Phrenic nerve or diaphragm irritation: Tumour, pleurisy, pneumonia, intrathoracic adenopathy, pericarditis, gastro-oesophageal reflux, oesophagitis
- Systemic causes: Alcohol intoxication, uraemia
- Other: Foreign body or insect in the ear. In infants it may be associated with apnoea or hyperventilation.

Folk remedies include aerophagia, breath holding, pharyngeal stimulation, distraction. Haloperidol, metaclopramide and several anaesthetic agents are also said to work.

Question: 66 of 100

Which of the following is true regarding sensory neural hearing loss?

(Please select 1 option)

○	Approximately 1 per 1000 children will have greater than 40db hearing loss.
○	The incidence is half as high in babies admitted to neonatal intensive care units compared with the normal population.
○	The risk is increased in children who have had post-natal rubella.
○	The risk is increased in Down syndrome.
○	The risk is increased in Werdnig-Hoffman syndrome.

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

○	Approximately 1 per 1000 children will have greater than 40db hearing loss. ← This is the correct answer
○	The incidence is half as high in babies admitted to neonatal intensive care units compared with the normal population.
○	The risk is increased in children who have had post-natal rubella.
◉	The risk is increased in Down syndrome. ✕ Incorrect answer selected
○	The risk is increased in Werdnig-Hoffman syndrome.

Sensory neural hearing loss is caused by lesions in the cochlea or the auditory nerve or central connections. It may be unilateral or bilateral. Language acquisition and secondary educational difficulties follow, with social isolation, and an increased risk of mental health problems. The approximate incidence is 1 per 1000 children.

Risk factors include:

- Neonatal intensive-care unit (NICU) admission: low birth weight, less than 32 weeks gestation, prolonged ventilation, prolonged jaundice, ototoxic drugs, hypoxic ischaemic encephalopathy, neonatal meningitis
- Congenital infection (rubella, cytomegalovirus [CMV])
- Dysmorphic syndromes (affecting head and neck)
- Family history of a close relative needing a hearing aid below the age of 5 years
- Infections: acute bacterial or TB meningitis, mumps (latter usually unilateral).

If all risk factors are considered, only around 50% of cases could be identified by testing between 5 and 10% of all babies.

Conductive hearing loss is related to middle ear pathology. This is commoner in Down syndrome, cleft palate, Turner's syndrome, and facial malformation syndromes.

Werdnig-Hoffman is associated with normal hearing.

Work Smart Session - MRCP Part 1

Question: 67 of 100

Which of the following is a form of generalised seizure?

(Please select 1 option)

- Automatisms
- Aversive seizures
- Benign rolandic epilepsy
- Epilepsia partialis continua
- Lennox-Gastaut syndrome

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

○	Automatisms
○	Aversive seizures
◉	Benign rolandic epilepsy ✕ Incorrect answer selected
○	Epilepsia partialis continua
○	Lennox-Gastaut syndrome ← This is the correct answer

Seizures may be classified as:

a) Partial

- Simple partial (consciousness retained), motor, sensory, autonomic, psychic
- Complex partial (consciousness impaired):
- Simple partial followed by impaired consciousness, or consciousness impaired at onset
- Partial seizures with secondary generalisation

b) Generalised seizures

- Absences (typical or atypical)
- Generalised tonic clonic
- Tonic
- Clonic
- Myoclonic
- Atonic
- Infantile spasms

- Simple partial (consciousness retained), motor, sensory, autonomic, psychic
- Complex partial (consciousness impaired):
- Simple partial followed by impaired consciousness, or consciousness impaired at onset
- Partial seizures with secondary generalisation

b) Generalised seizures

- Absences (typical or atypical)
- Generalised tonic clonic
- Tonic
- Clonic
- Myoclonic
- Atonic
- Infantile spasms

c) Unclassified aversive seizures are a form of simple partial seizure, consisting of head turning and conjugate eye movements.

Rasmussen's encephalitis is a subacute inflammatory encephalitis, and is one cause of epilepsia partialis continua.

Complex partial seizures often contain automatisms which may be elementary (including lip smacking, chewing, swallowing or salivation), or automatic behaviour (semi-purposive unco-ordinated or unplanned gestures including picking and pulling at clothing).

Rolandic epilepsy is a benign partial epilepsy associated with centro-temporal spikes. There is an excellent prognosis.

Question: 68 of 100

Which of the following forms of encephalitis is caused by a neuroimmunological response?

(Please select 1 option)

- ○ Cytomegalovirus
- ○ Enteral viruses
- ○ Herpes simplex
- ○ HIV infection
- ○ Measles

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which of the following forms of encephalitis is caused by a neuroimmunological response?

(Please select 1 option)

○	Cytomegalovirus
○	Enteral viruses
○	Herpes simplex
○	HIV infection
◉	Measles ✓ Correct

Encephalitis may be caused by:

- Direct invasion by a neurotoxic virus (encephalitis)
- Post-infectious encephalopathy: delayed brain swelling because of an immunological response to the antigen
- Slow virus infection, for example, human immunodeficiency virus [HIV] or subacute sclerosing panencephalitis [SSPE].

Direct infection is most commonly caused by enteral viruses, herpes simplex virus (HSV) 1 and 2, varicella, cytomegalovirus (CMV), and Epstein-Barr virus (EBV).

It is also occasionally caused by respiratory viruses, human herpes virus 6 (HHV6), rubella or mumps.

A post-infectious illness may also be caused by measles or varicella zoster (cerebellar ataxia).

Work Smart Session - MRCP Part 1

Question: 69 of 100

A young teenager presents with fever and headache. He has received oral amoxicillin for three days.

Which of the following cerebrospinal fluid (CSF) findings would virtually exclude a partially treated bacterial meningitis?

(Please select 1 option)

○	A CSF glucose of 45% of blood glucose
○	A negative CSF culture
○	A negative gram stain
○	A negative Kernig's Sign
○	A white cell count of 3

Submit answer | Skip question | Remove Tag | Remove question

A young teenager presents with fever and headache. He has received oral amoxicillin for three days.

Which of the following cerebrospinal fluid (CSF) findings would virtually exclude a partially treated bacterial meningitis?

(Please select 1 option)

○	A CSF glucose of 45% of blood glucose
○	A negative CSF culture
○	A negative gram stain
○	A negative Kernig's Sign
◉	A white cell count of 3 ✓ Correct

The assessment of children with suspected bacterial meningitis who have already received antibiotic therapy from their GP is a common diagnostic problem.

Partial treatment may reduce the incidence of positive CSF gram stains to < than 60%, and it also reduces the ability to grow the bacteria, particularly meningococcus.

CSF glucose, protein, neutrophils and bacterial antigen testing or polymerase chain reaction (PCR) should be completely unaffected. A normal white cell count would make the diagnosis very unlikely.

A 30-year-old lady who suffers from migraine complains that taking the recommended dose of paracetamol during an attack fails to relieve her headache. She has no other significant past medical history. She is a smoker of 15 cigarettes per day and also drinks alcohol 16 units per week.

Which of the following factors most likely explains the lack of efficacy of paracetamol in this lady?

(Please select 1 option)

○	Bacterial overgrowth
◉	Delayed gastric emptying ✓ Correct
○	First pass metabolism
○	p450 enzyme induction
○	p450 enzyme inhibition

"When salicylate absorption from effervescent aspirin tablets was studied during migraine, the rate of absorption was found to be reduced relative to that found in non-migrainous volunteers and in the same patients when headache-free. There is evidence that this reduced rate of absorption is caused by gastrointestinal stasis and reduced rate of gastric emptying. Patients in whom aspirin absorption was delayed were more likely to take longer to respond and to require additional treatment." Clin Pharmacokinet. 1978 Jul-Aug;3(4):313-8. Metoclopramide may be useful in accelerating gastric emptying.

The same has also been shown with paracetamol absorption. Br J Clin Pharmacol. 1984 Dec;18(6):867-71

Work Smart Session - MRCP Part 1

Question: 70 of 100

Which of the following clinical manifestations suggests Guillain-Barré (GB) syndrome?

(Please select 1 option)

○	Asymmetrical involvement of distal muscles
○	Brisk tendon reflexes
○	Bulbar involvement in about 50% of cases
○	Normal cerebrospinal fluid (CSF) protein
○	Weakness beginning in the arms

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

◉	Asymmetrical involvement of distal muscles ✕ Incorrect answer selected
○	Brisk tendon reflexes
○	Bulbar involvement in about 50% of cases ← This is the correct answer
○	Normal cerebrospinal fluid (CSF) protein
○	Weakness beginning in the arms

GB is a post-infectious polyneuropathy causing demyelination in mainly motor but also sensory nerves.

It usually follows a non-specific viral infection. Campylobacter and mycoplasma are recognised causes.

Weakness begins in the legs and progressively ascends to involve the trunk, upper limbs and finally the bulbar muscles (Landry's ascending paralysis).

Asymmetry is present in only 9% of patients, with symmetrical involvement being typical. Usually there is painless progression over days or weeks, but in cases of abrupt onset, there may be tenderness or muscle pain.

Bulbar involvement occurs in 50%, with a risk of aspiration and respiratory insufficiency can be problematic.

In the Miller Fisher syndrome there is external ophthalmoplegia, ataxia and areflexia.

In 20% of cases there is urinary incontinence or retention.

Clinical symptoms usually improve within two to three weeks, though a chronic relapsing form is recognised.

CSF protein is elevated to more than twice the upper limit of normal, with normal glucose and no pleocytosis. Bacterial cultures are negative and viral cultures rarely isolate anything.

The dissociation between a high CSF protein and a lack of cellular response in a person with an acute or subacute polyneuropathy is diagnostic of Guillain-Barre Syndrome.

Work Smart Session - MRCP Part 1

Question: 71 of 100

A 35-year-old female presents with headaches. Examination reveals papilloedema.

Which of the following would make the diagnosis of benign intracranial hypertension (BIH) unlikely?

(Please select 1 option)

○	Absence of retinal venous pulsations
◉	Bilateral upgoing plantar responses ✓ Correct
○	Normal ventricles on CT or MRI scan
○	Reduced visual acuity
○	Sixth cranial nerve palsy

BIH is typically associated with papilloedema, reduced venous pulsation and normal appearances of the magnetic resonance imaging (MRI).

A VIth nerve palsy is a recognised association.

Reflexes are preserved and plantars are flexor.

Extensor plantars suggest a alternative diagnosis.

Work Smart Session - MRCP Part 1

Question: 72 of 100

A 54-year-old female is admitted with progressive weakness following a trivial flu-like illness.

Which of the following would exclude Guillain-Barre Syndrome (GBS) as the diagnosis?

(Please select 1 option)

○	Autonomic dysfunction
○	Elevated protein on CSF examination
○	Evidence of muscle wasting
○	Ophthalmoplegia
○	Sensory level below T1

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 54 year old female is admitted with progressive weakness following a trivial flu like illness.

Which of the following would exclude Guillain-Barre Syndrome (GBS) as the diagnosis?

(Please select 1 option)

○	Autonomic dysfunction
○	Elevated protein on CSF examination
○	Evidence of muscle wasting
○	Ophthalmoplegia
◉	Sensory level below T1 ✓ Correct

GBS is a post-infectious acute polyneuritis typified by elevated cerebral spinal fluid (CSF) protein with few cells and often normal glucose.

There is a profound weakness associated with areflexia and peripheral sensory neuropathy.

Ophthalmoplegia is associated in particular with the Miller-Fisher variant.

However, a sensory level is NOT a feature and would suggest cervical myelopathy.

Muscle wasting is typical with prolonged illness.

Autonomic disease may also feature.

Question: 73 of 100

Which of the following is a true of myasthenia gravis (MG)?

(Please select 1 option)

○	There is a strong association with anti-noradrenergic receptor antibodies
○	Neurotransmitter released at the motor end plate is greatly reduced
○	Repetitive stimulation of a motor nerve produces a reduction in the amplitude of the 5th response compared with the 1st in 98% of cases(electrodecremental test)
○	Electrical recordings of single motor unit activity commonly reveal variation in the latency of the various mucle fibre responses(jitter)
○	Subjective improvement in muscle strength following edrophonium is diagnostic of the condition

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Question: 73 of 100

Which of the following is a true of myasthenia gravis (MG)?

(Please select 1 option)

○	There is a strong association with anti-noradrenergic receptor antibodies
○	Neurotransmitter released at the motor end plate is greatly reduced
○	Repetitive stimulation of a motor nerve produces a reduction in the amplitude of the 5th response compared with the 1st in 98% of cases(electrodecremental test)
○	Electrical recordings of single motor unit activity commonly reveal variation in the latency of the various mucle fibre responses(jitter) ← This is the correct answer
◉	Subjective improvement in muscle strength following edrophonium is diagnostic of the condition ✕ Incorrect answer selected

Anti-acetylcholine receptor antibodies are typically found resulting in reduced ACh receptor numbers but sufficient neurotransmitter is released.

An increase in decrement on stimulation at 3Hz is detectable in some patients.

Jitter is the most sensitive emg index in MG but is not specific of the condition. The nerve conductions and electromyogram (EMG) studies are usually normal in myasthenia gravis, but the repetitive stimulation of a nerve may demonstrate decrements of the muscle action potential (far less than 98%).

Although improved muscle strength after edrophonium is seen, it is not diagnostic but depends more on the clinical presentation and presence of AChR ab.

Question: 74 of 100

Which of the following is a recognised cause of a phrenic nerve palsy?

(Please select 1 option)

○	Aortic aneurysm ← This is the correct answer
○	Dermoid
○	Ganglioneuroma
◉	Pericardial cyst ✕ Incorrect answer selected
○	Sarcoidosis

The diaphragm is innervated by the phrenic nerve (C3,4,5).

Palsy is a recognised complication of thoracic surgery, infection, Guillain-Barre or invasion by an adjacent tumour.

It may also be stretched by an aortic aneurysm.

Work Smart Session - MRCP Part 1

Question: 76 of 100

Which of the following is a characteristic feature of transient global amnesia?

(Please select 1 option)

○	Abnormal behaviour
○	Apraxia
○	Confabulation
○	Loss of personal identity
○	Normal perception

Submit answer | Skip question | Remove Tag | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which of the following is a characteristic feature of transient global amnesia?

(Please select 1 option)

○	Abnormal behaviour
○	Apraxia
○	Confabulation
○	Loss of personal identity
◉	Normal perception ✓ Correct

Transient global amnesia (TGA) is a syndrome in which a previously well person suddenly becomes confused and amnesic.

The person appears bewildered and repeatedly asks questions about present and recent events, for example, "Where am I?"

TGA is characterised by the brain's sudden inability to form new memory traces (antrograde amnesia) plus retrograde memory loss for events of the preceding days, weeks or in some cases years.

During the attack, which affects both verbal and nonverbal memory, the patient is bewildered and anxious.

Self identification is preserved.

Behaviour is otherwise normal and appropriate.

'Characteristic' means that absence of the symptom would make you doubt the diagnosis. The presence of any of the other suggested options would suggest an alternative diagnosis.

Question: 77 of 100

A 21-year-old man recovered from the immediate effects of a head injury sustained in a motor cycle accident three months previously.

Which one of the following is the most likely delayed consequence of severe traumatic brain injury?

(Please select 1 option)

○	Episodic hypersomnia
○	Multiple obsessional symptoms
◉	Outbursts of aggressive behaviour ✕ Incorrect answer selected
○	Pathological jealousy
○	Persistent anxiety ← This is the correct answer

The condition is post-concussion syndrome and although many of the symptoms given may be seen the commonest one (headache) has been left out!

"The most common symptoms are headache and neck discomfort; changes in memory, concentration, and attention; dizziness; irritability, depression or anxiety; and sleep disturbance, among other symptoms."

There is

- A disturbance of thought
- A poor concentration span and
- Subjects are easily distracted.

Anxiety would seem the most common and therefore the most likely answer.

Question: 78 of 100

Which of the following is least likely to cause choreiform movements?

(Please select 1 option)

◉	Polyarteritis nodosa ✓ Correct
○	Polycythaemia rubra vera
○	Rheumatic fever
○	Systemic lupus erythematosus
○	Thyrotoxicosis

PAN affects medium sized arteries and usually involves peripheral nerves, bowel and rarely lungs.

Other causes of chorea are Huntington's chorea, rheumatic fever and senile chorea.

Question: 79 of 100

Which of the following features are not compatible with the diagnosis of motor neurone disease (MND)?

(Please select 1 option)

○	Dementia
○	Dysphagia
○	Muscle cramps
○	Neck weakness
◉	Optic atrophy ✓ Correct

10% of patients with MND have dementia (frontotemporal).

Optic atrophy is not a feature of MND.

Other features not compatible with the diagnosis are sensory impairment and bladder dysfunction.

A 36-year-old police officer presents with a three day history of slurred speech. She also complains of double vision and a sensation of breathlessness.

The oxygen saturations are 99% on air. Neurological examination reveals normal power, reflexes and plantar responses.

Which of the following would improve symptoms in this presentation?

(Please select 1 option)

○	G-CSF
◉	Edrophonium ✓ Correct
○	Non-steroidal anti-inflammatory drugs
○	Physiotherapy
○	Plasmapheresis

This lady has symptoms suggesting myasthenia gravis.

Her breathlessness is probably secondary to anxiety about the symptoms and associated hyperventilation.

Edrophonium (Tensilon) is sometimes used in the diagnosis of myasthenia gravis and would be expected temporarily to improve symtpoms.

Examination demonstrates pyrexia, neck stiffness, photophobia, dysarthria, nystagmus and ataxia. CSF shows neutrophilic pleocytosis, low glucose, elevated protein.

What is the most likely diagnosis?

(Please select 1 option)

○	Carcinomatosis meningitis
○	Cryptococcal meningitis
◉	Listeria meningitis ✓ Correct
○	Meningococcal meningitis
○	Tuberculus meningitis

Risk factors for listeria meningitis include older age and immunosuppresion.

It is typically associated with brain stem signs.

Cerebrospinal fluid shows

- Neutrophilic pleocytosis
- Low glucose and
- High protein.

Work Smart Session - MRCP Part 1

Question: 81 of 100

Which of the following investigations best supports a diagnosis of new variant CJD?

(Please select 1 option)

○	CSF analysis
○	CT brain
○	EMG
○	MRI brain
○	VEPs

Work Smart Session - MRCP Part 1

Question: 81 of 100

Which of the following investigations best supports a diagnosis of new variant CJD?

(Please select 1 option)

○	CSF analysis
○	CT brain
○	EMG
◉	MRI brain ✓ Correct
○	VEPs

MRI brain typically shows bilateral posterior thalamic high signal abnormalities in a patient with new variant Creutzfeldt-Jakob disease (CJD).

Cerebrospinal fluid (CSF) analysis only shows non-specific changes.

EMG and CT brain are normal.

Sporadic CJD (and not new variant CJD) is associated with specific EEG changes.

Work Smart Session - MRCP Part 1

Question: 82 of 100

For which of the following could a right carotid artery stenosis not account?

(Please select 1 option)

○	Contralateral hemiplegia
○	Contralateral hemisensory loss
○	Drop attacks ← This is the correct answer
◉	Dysphasia ✕ Incorrect answer selected
○	Right amaurosis fugax

Carotid artery disease causes

- Contralateral hemiplegia
- Hemisensory loss
- Homonymous hemianopia
- Dysphasia (right)
- Hemineglect (left).

Drop attacks are due to vertebrobasilar insufficiency.

Time taken: 5 hrs 9 mins 35 secs

Work Smart Session - MRCP Part 1

Question: 83 of 100

A 75-year-old woman presents with acute monocular visual loss.

Fundoscopy reveals a swollen pale optic disc in the affected eye.

What is the mose likely diagnosis?

(Please select 1 option)

- Central retinal vein occlusion.
- Closed angle glaucoma.
- Giant cell arteritis.
- Optic neuritis.
- Raised intracranial pressure.

Submit answer | Skip question | Tag Question | Remove question

Time taken: 5 hrs 10 mins 51 secs

Work Smart Session - MRCP Part 1

Question: 83 of 100

A 75-year-old woman presents with acute monocular visual loss.

Fundoscopy reveals a swollen pale optic disc in the affected eye.

What is the mose likely diagnosis?

(Please select 1 option)

◉	Central retinal vein occlusion. ✕ Incorrect answer selected
○	Closed angle glaucoma.
○	Giant cell arteritis. ← This is the correct answer
○	Optic neuritis.
○	Raised intracranial pressure.

The presence of a swollen optic disc suggests ischaemic optic neuropathy.

In elderly people giant cell arteritis is a common presentation of acute monocular visual loss.

Optic neuritis is very rare in people over the age of 50.

You will expect bilateral swollen optic discs in raised intracranial pressure.

In central retinal vein occlusion you will expect diffuse retinal haemorrhages.

Time taken: 5 hrs 10 mins 51 secs

Work Smart Session - MRCP Part 1

Question: 84 of 100

A 36-year-old man has a three month history of pain in his feet and lower legs. He was diagnosed as having diabetes at age 14 and treated with insulin. He is a cannabis smoker and drinks 30 units of alcohol per week.

On examination he has impaired pain and temperature sensation in feet and lower legs, normal joint position and vibration sense. His reflexes are normal.

What is the diagnosis?

(Please select 1 option)

○	Alcoholic polyneuropathy.
○	Chronic inflammatory demyelinating polyneuropathy (CIDP)
○	Diabetic polyneuropathy.
○	Syringomyelia.
○	Vitamin B12 deficiency.

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Question: 84 of 100

A 36-year-old man has a three month history of pain in his feet and lower legs. He was diagnosed as having diabetes at age 14 and treated with insulin. He is a cannabis smoker and drinks 30 units of alcohol per week.

On examination he has impaired pain and temperature sensation in feet and lower legs, normal joint position and vibration sense. His reflexes are normal.

What is the diagnosis?

(Please select 1 option)

◉	Alcoholic polyneuropathy. ✕ Incorrect answer selected
○	Chronic inflammatory demyelinating polyneuropathy (CIDP)
○	Diabetic polyneuropathy. ← This is the correct answer
○	Syringomyelia.
○	Vitamin B12 deficiency.

The history suggests small fibre painful peripheral sensory neuropathy. The comonest cause is diabetes.

Vitamin B12 deficiency causes impairment of joint position and vibration. Chronic inflammatory demyelinating polyneuropathy (CIDP) causes a large fibre peripheral neuropathy with areflexia.

In syringomyelia you have impaired pain and temperature only in the upper limbs.

Typically with alcoholic polyneuropathy all fibre types are affected and it is seen with a higher alcohol consumption than 30 units.

Work Smart Session - MRCP Part 1

Question: 85 of 100

The anticonvulsant Levetiracetam

(Please select 1 option)

○	Acts via the gamma-aminobutyric acid (GABA) receptor
○	Is associated with increased plasma concentrations of sodium valproate
○	Is associated with induction of hepatic cytochrome p450 enzymes
○	Is used as monotherapy for the treatment of generalised convulsions
○	Is well absorbed via the oral route

Work Smart Session - MRCP Part 1

Question: 85 of 100

The anticonvulsant Levetiracetam

(Please select 1 option)

○	Acts via the gamma-aminobutyric acid (GABA) receptor
○	Is associated with increased plasma concentrations of sodium valproate
○	Is associated with induction of hepatic cytochrome p450 enzymes
○	Is used as monotherapy for the treatment of generalised convulsions
◉	Is well absorbed via the oral route ✓ Correct

Levetiracetam (Keppra) is an adjunctive treatment for partial seizures with or without secondary generalisation. Its mechanism of action is unknown.

It is rapidly absorbed orally, it does not effect hepatic enzymes but dose reduction is required in renal failure.

The drug appears to be well tolerated with few side effects.

Time taken: 5 hrs 14 mins 57 secs

Work Smart Session - MRCP Part 1

Question: 86 of 100

A 65-year-old man has a monotonous, slurred speech. He has an expressionless face and a festinant gait.

There is also impairment of vertical gaze.

What is the most likely underlying aetiology?

(Please select 1 option)

○	Cerebrovascular disease
○	Idiopathic
○	Shy-Drager syndrome
○	Steele-Richardson-Olszewski syndrome
○	Wilson's disease

Submit answer | Skip question | Tag Question | Remove question

What is the most likely underlying aetiology?

(Please select 1 option)

○	Cerebrovascular disease
○	Idiopathic
◉	Shy-Drager syndrome ✕ Incorrect answer selected
○	Steele-Richardson-Olszewski syndrome ← This is the correct answer
○	Wilson's disease

Parkinson's disease is a triad of

- Bradykinesia
- Tremor and
- Rigidity.

Speech may be slurred and without accents or emphasis. Impairment of vertical gaze suggests the diagnosis of Steele-Richardson-Olszewski syndrome or supranuclear gaze palsy, which also cause pyramidal signs, dementia or frontal lobe syndrome.

Response to L-dopa is poor and median survival is about seven years.

Shy-Drager syndrome is associated with autonomic dysfunction and postural hypotension.

Wilson's disease presents in children and young adults with cirrhosis and parkinsonism, which later leads to dementia, dysphagia and immobility.

Work Smart Session - MRCP Part 1

Question: 87 of 100

Are the following true concerning baclofen?

(Please select 1 option)

○	Acts directly on skeletal muscle
○	Causes hallucinations when withdrawn ← This is the correct answer
◉	Causes rhabdomyolysis ✕ Incorrect answer selected
○	Reduces Ca^{2+} release from sarcoplasmic reticulum
○	Reduces cerebral but not spinal spasticity

The primary site of action is the spinal cord by depressing monosynaptic and polysynaptic transmission. It can hyperpolarise cells by increasing K^{+} conductance and inhibit Ca^{2+} channels in others.

Rhabdomyolysis is caused by

- Clofibrate
- Aminocaproic acid
- HMG-CoA reductase inhibitors
- Neuroleptics (neuroleptic malignant syndrome).

Avoid abrupt withdrawal as it can cause serious side-effects including autonomic dysreflexia.

Time taken: 5 hrs 17 mins 30 secs

Work Smart Session - MRCP Part 1

Question: 88 of 100

A 25-year-old female presents with a two day history of diplopia and unsteadiness.

Two weeks ago she suffered an upper respiratory tract infection.

On examination there is complete ophthalmoplegia, areflexia and gait ataxia.

Which of the following blood tests is the most likely to confirm the underlying diagnosis?

(Please select 1 option)

- Acetylcholine receptors antibodies
- Anti GM1 antibodies
- Anti GQib antibodies
- Anti Hu antibodies
- Anti purkinje cell antibodies

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Acetylcholine receptors antibodies
◉	Anti GM1 antibodies ✕ Incorrect answer selected
○	Anti GQib antibodies ← This is the correct answer
○	Anti Hu antibodies
○	Anti purkinje cell antibodies

The most likely diagnosis is Miller Fisher syndrome (variant of Guillain-Barre syndrome). It consists of complete or partial ophthalmoplegia, areflexia and ataxia. It usually follows antecedent infections. Serum IgG antibody to the ganglioside GQib is present in more than 95% of patients. It is highly specific for the syndrome.

Elevated levels of antibodies to the glycolipid ganglioside-monosialic acid (GM1 antibodies) have been shown in some instances to be associated with certain neurological disorders:

- Lower motor neuron syndromes
- Amyotrophic lateral sclerosis
- Multiple sclerosis
- Other multifocal neuropathies and
- Systemic lupus erythematosus (SLE) with central nervous system involvement.

Neuronal nuclear (Hu) antibodies (NNA) are found in a number of paraneoplastic syndromes, including

- Subacute sensory neuronopathy
- Paraneoplastic encephalomyelitis and
- Paraneoplastic cerebellar degeneration

and are associated with small cell lung carcinoma.

Purkinje cell cytoplasmic antibodies are useful for identifying individuals with subacute cerebellar degeneration or peripheral neuropathy due to a remote (autoimmune) effect of gynecologic or breast carcinoma.

Work Smart Session - MRCP Part 1

Question: 89 of 100

A 65-year-old man presents with four months history of swallowing difficulties (worse with liquids than solids).

He also complains of nasal regurgitation, coughing and choking episodes during meals and slight dysarthria. He lost one stone over the last eight weeks.

Which of the following investigations is the most appropriate for this case?

(Please select 1 option)

◉	Acetyl choline receptors antibodies ✓ Correct
○	Barium swallow
○	CXR
○	Gastroscopy
○	Tumour markers

Nasal regurgitation, coughing and choking episodes during meals, dysphagia that is worse with liquids than solids and dysarthria indicate neurogenic dysphagia.

Important causes at this age include myasthenia gravis and motor neuron disease.

Mechanical dysphagia (for example, oesophageal and gastric carcinoma, oesophageal stricture, etc) causes dysphagia that is worse with solids than liquids.

Nasal regurgitation and dysarthria are not accompanying features of mechanical dysphagia.

Next question

Rate this question

A 50-year-old man has drunk six units of alcohol a day for most of his adult life.

He has worsening symptoms of difficulty walking, headaches and urinary incontinence for the past ten months.

Of the following which is the most likely diagnosis?

(Please select 1 option)

○	Encephalopathy
○	Meningovascular syphilis
◉	Normal pressure hydrocephalus ✕ Incorrect answer selected
○	Syringomyelia ← This is the correct answer
○	Wernicke-Korsakoff syndrome

There is no suggestion of memory loss so normal pressure hydrocephalus and Wernicke-Korsakoff syndrome are less likely.

Encephalopathy is more likely to be associated with symptoms of drowsiness.

Although meningovascular syphilis can present in many different forms it is rather rare.

Syringomyelia is associated with headaches, motor and bladder symptoms and is the likely diagnosis.

In this scenario, the alcohol is a distractor.

Question: 90 of 100

A 68-year-old man presents with progressive visual impairment. On examination there is an incongruous homonymous hemianopia.

The most likely anatomical site of the neurological lesion is at:

(Please select 1 option)

○	chiasma
○	occipital lobe
○	optic nerve
○	optic radiation
◉	optic tract ✓ Correct

Optic neuropathy causes:

- a central scotoma
- an optic tract lesion
- an incongruous homonymous haemianopia
- a chiasmal lesion
- a bitemporal haemianopia
- an optic radiation and occipital lobe lesion
- a congruous homonymous hemianopia.

Time taken: 5 hrs 23 mins 22 secs

Work Smart Session - MRCP Part 1

Question: 92 of 100

A 45-year-old man presents with an insidious onset of binocular horizontal diplopia and left sided facial pain.

On examination he has a left abducens nerve palsy and numbness over the maxillary division of the left trigeminal nerve.

Of the following which is the most likely anatomical site of his neurological lesion?

(Please select 1 option)

- Cavernous sinus
- Cerebellopontine angle
- Midbrain
- Petrous apex
- Superior orbital fissure

Submit answer | Skip question | Tag Question | Remove question

- Shop
- Help

Of the following which is the most likely anatomical site of his neurological lesion?

(Please select 1 option)

○	Cavernous sinus
○	Cerebellopontine angle
○	Midbrain
◉	Petrous apex ✓ Correct
○	Superior orbital fissure

In the pre-antibiotic era an abducens nerve palsy with ipsilateral pain and numbness was due to petrous osteitis (Gradenigo syndrome) but is now more likely the result of a meningioma or nasopharyngeal carcinoma of the petrous apex.

The cavernous sinus syndrome consists of variable involvement of

- Oculomotor
- Trochlear
- Abducens
- Trigeminal (ophthalmic and maxillary division) and
- Oculo-sympathetic nerves.

The superior orbital fissure syndrome is similar to the cavernous sinus syndrome except for the presence of proptosis.

Question: 93 of 100

A female patient aged 30 has a five year history of difficulty getting upstairs and out of a low chair and mild upper limb weakness but no pain. There is no family history.

She presented with severe type 2 respiratory failure. EMG showed evidence of myopathy.

Which is the most likely diagnosis?

(Please select 1 option)

○	Acid maltase deficiency
○	Inclusion body myositis
○	Lambert-Eaton myasthenic syndrome
○	Miller-Fisher syndrome
○	Polymyositis

Submit answer | Skip question | Tag Question | Remove question

Question: 93 of 100

A female patient aged 30 has a five year history of difficulty getting upstairs and out of a low chair and mild upper limb weakness but no pain. There is no family history.

She presented with severe type 2 respiratory failure. EMG showed evidence of myopathy.

Which is the most likely diagnosis?

(Please select 1 option)

○	Acid maltase deficiency ← This is the correct answer
○	Inclusion body myositis
○	Lambert-Eaton myasthenic syndrome
○	Miller-Fisher syndrome
◉	Polymyositis ✕ Incorrect answer selected

Acid maltase deficiency typically presents with insidious onset of proximal myopathy and early respiratory muscle weakness.

Respiratory failure in inflammatory myopathies (polymyositis, dermatomyositis, inclusion body myositis) and limb girdle muscular dystrophy are rare. Muscle biopsy shows vacuolation in muscle fibres.

Miller-Fisher syndrome, a variant of Guillain-Barré syndrome, is characterised by ophthalmoplegia, ataxia and areflexia.

Lambert-Eaton myasthenic syndrome, often a paraneoplastic phenomenon, is associated with hyporeflexia which returns after exercise, autonomic symptoms and fatiguability.

Work Smart Session - MRCP Part 1

Question: 94 of 100

A 60-year-old man awakens with painless loss of vision of his left eye.

Three years earlier he had suffered a similar episode involving the right eye. Visual loss in that eye has been stationary. He does not complain of any systemic symptoms.

What is the most likely diagnosis?

(Please select 1 option)

○	Acute angle-closure glaucoma
○	Arteritic ischaemic optic neuropathy
○	Compressive optic neuropathy
○	Nonarteritic ischaemic optic neuropathy
○	Optic neuritis

Submit answer | Skip question | Tag Question | Remove question

A 60-year-old man awakens with painless loss of vision of his left eye.

Three years earlier he had suffered a similar episode involving the right eye. Visual loss in that eye has been stationary. He does not complain of any systemic symptoms.

What is the most likely diagnosis?

(Please select 1 option)

◉	Acute angle-closure glaucoma ✕ Incorrect answer selected
○	Arteritic ischaemic optic neuropathy
○	Compressive optic neuropathy
○	Nonarteritic ischaemic optic neuropathy ← This is the correct answer
○	Optic neuritis

Sudden onset of painless monocular visual loss in patients aged 50 or more is commonly due to ischaemic optic neuropathy.

Commonly the symptoms are first noticed upon awakening in the morning. The fellow eye may suffer a similar event within 5 years.

There are no systemic features (weight loss, lethargy, malaise, jaw claudication, scalp tenderness) to suggest arteritic ischaemic optic neuropathy (giant cell arteritis). In giant cell arteritis, the fellow eye is usually affected within four weeks.

Optic neuritis is unlikely in a man of this age who had painless loss of vision.

Work Smart Session - MRCP Part 1

Question: 95 of 100

A broad-based ataxic gait occurs characteristically with:

(Please select 1 option)

○	Basal ganglia lesion
○	Cerebellar vermis lesion
○	Phenytoin toxicity
○	Proximal myopathy
○	Right-sided cerebral infarction

Submit answer | Skip question | Tag Question | Remove question

Time taken: 5 hrs 30 mins 31 secs

Work Smart Session - MRCP Part 1

Question: 95 of 100

A broad-based ataxic gait occurs characteristically with:

(Please select 1 option)

○	Basal ganglia lesion
○	Cerebellar vermis lesion
◉	Phenytoin toxicity ✓ Correct
○	Proximal myopathy
○	Right-sided cerebral infarction

Broad based gait is associated with cerebellar syndrome. However, lesions of cerebellar vermis cause truncal ataxia and tendency to fall backwards.

Basal ganglia disease causes extrapyramidal signs with Parkinsonism (festinant gait, marche à petits pas).

Proximal myopathy causes a waddling gait.

Right-sided cerebral infarction is associated with a hemiplegic gait.

Causes of dilated pupils include:

(Please select 1 option)

○	Argyll Robertson pupil
○	Ethylene glycol poisoning
○	Myotonic dystrophy
○	Organophosphate poisoning
○	Pontine haemorrhage

Submit answer | Skip question | Tag Question | Remove question

(Please select 1 option)

○	Argyll Robertson pupil
◉	Ethylene glycol poisoning ✓ Correct
○	Myotonic dystrophy
○	Organophosphate poisoning
○	Pontine haemorrhage

Causes of dilated pupils include:

- Holmes-Adie (myotonic) pupil

- third nerve palsy

- drugs and poisons (atropine, cobalt [CO], ethylene glycol).

Causes of small pupils include:

- Horner's syndrome

- old age

- pontine haemorrhage

- Argyll Robertson pupil

- drugs and poisons (opiates, organophosphates).

A 25-year-old woman presents with a severe migraine.

Which of the following is not a recognised feature of migraine?

(Please select 1 option)

○	Bilateral fortification spectra
○	External ophthalmoplegia
○	Precipitation by oral contraceptives
○	Some symptoms improved by tricyclic antidepressants
○	Third nerve palsy

Submit answer | Skip question | Tag Question | Remove question

Time taken: 5 hrs 31 mins 48 secs

Work Smart Session - MRCP Part 1

Question: 97 of 100

A 25-year-old woman presents with a severe migraine.

Which of the following is not a recognised feature of migraine?

(Please select 1 option)

◉	Bilateral fortification spectra ✕ Incorrect answer selected
○	External ophthalmoplegia ← This is the correct answer
○	Precipitation by oral contraceptives
○	Some symptoms improved by tricyclic antidepressants
○	Third nerve palsy

Fortification spectra (jagged lines resembling battlements) and teichopsia (flashes) are common. Tricyclics can be useful for nausea.

Third nerve palsy is seen in ophthalmoplegic migraine.

Chronic progressive external ophthalmoplegia usually develops in childhood and is associated with ptosis, fatigue and limitation to eye- movements in all directions.

The disorder is in the cytochromes.

Question: 98 of 100

Which of the following will not be affected by a lesion of the facial nerve in the internal auditory meatus?

(Please select 1 option)

○	Blinking
○	Hearing
○	Lacrimation
○	Sweating over the cheek
○	Taste

Submit answer | Skip question | Tag Question | Remove question

Time taken: 5 hrs 32 mins 23 secs

Work Smart Session - MRCP Part 1

Question: 98 of 100

Which of the following will not be affected by a lesion of the facial nerve in the internal auditory meatus?

(Please select 1 option)

○	Blinking
○	Hearing
○	Lacrimation
○	Sweating over the cheek ← This is the correct answer
◉	Taste ✕ Incorrect answer selected

The extent of dysfunction depends on the level of injury.

If it is proximal to geniculate ganglion, for example, internal auditory meatus, taste is lost in the anterior 2/3 of tongue. Also secretion from submandibular, sublingual and lacrimal glands is impaired.

Hyperacusis is due to paralysis of stapedius. Orbicularis oculi is affected causing inability to blink/close eyelids.

Sensation over face is supplied by the trigeminal nerve, and sweat glands are controlled by sympathetic nervous system, for example, anhydriosis in Horner's syndrome.

Work Smart Session - MRCP Part 1

Question: 99 of 100

The incidence of Down syndrome in children born to women aged less than 30 years is approximately which of the following?

(Please select 1 option)

○	1:500
○	1:1000 ← This is the correct answer
◉	1:5000 ✕ Incorrect answer selected
○	1:10000
○	1:15000

The incidence is roughly 1 in 1200 births for woman less than 30 and this incidence can rise to 1 in 60 by the age of 42.

Maternal age also affects the incidence of hydrocephalus, anencephaly and other chromosomal disorders.

Question: 9 of 100

A 62-year-old male presents with weakness of the right hand. You note global wasting of the small hand muscles, there is also sensory loss over the medial border of the forearm around the elbow.

Which nerve root is damaged?

(Please select 1 option)

○	C5
○	C6
○	C7
○	C8
◉	T1 ✓ Correct

This patient has Klumpke's paralysis due to damage to the T1 nerve root. This root eventually supplies the median and ulnar nerves.

The ulnar nerve supplies all of the intrinsic hand muscles except for those of the thenar eminence and the first and second lumbricals which are innervated by the median nerve.

Work Smart Session - MRCP Part 1

Time taken:

Question: 1 of 47

A 72-year-old man with a history of type 2 diabetes mellitus and multiple transient ischaemic attacks (TIAs) comes to the hospital complaining of visual field loss. He says this happened suddenly and he woke up with problems with his vision the morning before coming to the emergency department.

Medication includes clopidogrel, ramipril, atorvastatin, and metformin.

On examination his BP is 165/100 mmHg, his pulse is 76 and regular. Visual field examination reveals a right homonymous upper quadrantanopia.

Where is the most likely site for the underlying lesion?

(Please select 1 option)

○	Left occipital lobe
○	Left temporal lobe
○	Optic chiasm
○	Right optic nerve
○	Right temporal lobe

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 21 mins 57 secs

Question: 10 of 47

A 37-year-old homosexual male presented to the medical take with an acute onset of reduced vision in his left eye.

Fundoscopy of the left eye revealed an extensive 'brushfire-like' lesion in the major superior temporal arcade with a large patch of white fluffy lesion mixed with extensive retinal haemorrhages.

What is the most likely diagnosis?

(Please select 1 option)

○	CMV retinitis
○	Ocular histoplasmosis
○	Syphilitic choroiditis
○	Syphilitic neuroretinitis
○	Tuberculous periphlebitis

Submit answer | Skip question | Tag Question | Remove question

A 37-year-old homosexual male presented to the medical take with an acute onset of reduced vision in his left eye.

Fundoscopy of the left eye revealed an extensive 'brushfire-like' lesion in the major superior temporal arcade with a large patch of white fluffy lesion mixed with extensive retinal haemorrhages.

What is the most likely diagnosis?

(Please select 1 option)

◉	CMV retinitis ✓ Correct
○	Ocular histoplasmosis
○	Syphilitic choroiditis
○	Syphilitic neuroretinitis
○	Tuberculous periphlebitis

This is a classic example of *Cytomegalovirus* (CMV) retinitis secondary to human immunodeficiency virus (HIV), as is suggestive of the information given in this scenario.

Ocular histoplasmosis and syphilitic choroiditis would give a fundus picture of multiple whitish lesions.

Syphilitic neuroretinitis would normally give a picture of a macular star exudation.

Tuberculous periphlebitis is the next closest answer, but does not fit the description of 'brushfire-like' lesion in that it gives a picture of perivenous sheathing and minimal retinal haemorrhages.

Work Smart Session - MRCP Part 1

Time taken: 27 mins

Question: 11 of 47

Which one of the following diseases is most likely to be associated with scleritis?

(Please select 1 option)

○	Ankylosing spondylitis
○	Crohn's disease
◉	Rheumatoid arthritis ✓ Correct
○	SLE
○	Ulcerative colitis

Rheumatoid arthritis is associated with scleritis, whereas the other choices are more associated with anterior uveitis.

Work Smart Session - MRCP Part 1

Time taken: 27 mins

Question: 12 of 47

A 23-year-old man with an otherwise insignificant past medical history, presented with a sharp painful left eye over the last one day.

Ocular examination revealed a left mildly red eye with mild reduction of visual acuity.

There were no ocular discharges to note.

What is the most likely diagnosis?

(Please select 1 option)

- Episcleritis
- Herpetic keratitis
- Iritis
- Posterior uveitis
- Scleritis

Submit answer | Skip question | Tag Question | Remove question

A 23-year-old man with an otherwise insignificant past medical history, presented with a sharp painful left eye over the last one day.

Ocular examination revealed a left mildly red eye with mild reduction of visual acuity.

There were no ocular discharges to note.

What is the most likely diagnosis?

(Please select 1 option)

○	Episcleritis
○	Herpetic keratitis ← This is the correct answer
◉	Iritis ✕ Incorrect answer selected
○	Posterior uveitis
○	Scleritis

Any of the above given diagnoses can occur in a young man, but the history is that of a sharp painful eye, as opposed to a dull achy eye.

Any sharp ocular pain is more suggestive of corneal/ocular surface pathologies, and hence herpetic keratitis is the best answer.

Work Smart Session - MRCP Part 1

Time taken: 28 mins 16 secs

Question: 13 of 47

A 65-year-old hypermetropic lady was seen in an acute unselected medical take.

She presented with a three hour history of dull pain, lacrimation, photophobia and reduced vision in the right eye.

She had no significant past medical history.

Ocular examination revealed a painful red eye with an oval shaped pupil.

What is the most likely diagnosis?

(Please select 1 option)

- Acute angle closure glaucoma
- Episcleritis
- Iritis
- Keratoconjunctivitis
- Scleritis

Submit answer | Skip question | Tag Question | Remove question

A 65-year-old hypermetropic lady was seen in an acute unselected medical take.

She presented with a three hour history of dull pain, lacrimation, photophobia and reduced vision in the right eye.

She had no significant past medical history.

Ocular examination revealed a painful red eye with an oval shaped pupil.

What is the most likely diagnosis?

(Please select 1 option)

◉	Acute angle closure glaucoma ✓ Correct
○	Episcleritis
○	Iritis
○	Keratoconjunctivitis
○	Scleritis

Red eye of an acute painful dull nature, with photophobia and reduced vision in a hypermetropic person is highly indicative of acute angle closure glaucoma.

The pupil in this condition is usually mid-dilated oval shaped.

The oval shape is due to the iris sphincter ischaemia from the high intraocular pressure.

Work Smart Session - MRCP Part 1

Time taken: 30 mins 49 secs

Question: 14 of 47

A 45-year-old asthmatic man presented with bilateral blurry vision of gradual onset over the last two months.

On examination he was found to have bilateral posterior subcapsular cataract, more so in the right than the left.

His other past medical history was that he had galactosaemia when he was still a baby, but this has since been treated. He is on bronchodilator inhalers and steroid inhalers to control his asthma. His oral medication includes amiodarone, aspirin and simvastatin.

What is the most likely cause of his cataracts?

(Please select 1 option)

○	Amiodarone
○	Galactosaemia
○	Inhaled bronchodilators
○	Inhaled steroids
○	Simvastatin

Submit answer | Skip question | Tag Question | Remove question

On examination he was found to have bilateral posterior subcapsular cataract, more so in the right than the left.

His other past medical history was that he had galactosaemia when he was still a baby, but this has since been treated. He is on bronchodilator inhalers and steroid inhalers to control his asthma. His oral medication includes amiodarone, aspirin and simvastatin.

What is the most likely cause of his cataracts?

(Please select 1 option)

◉	Amiodarone ✕ Incorrect answer selected
○	Galactosaemia
○	Inhaled bronchodilators
○	Inhaled steroids ← This is the correct answer
○	Simvastatin

Inhaled steroids can cause cataracts.

Amiodarone causes vortex keratopathy.

Galactosaemia also does cause cataracts, but if the galactosaemia is treated, the cataract is reversible.

Inhaled bronchodilators and simvastatin are not known to cause cataracts.

Work Smart Session - MRCP Part 1

Time taken: 32 mins 53 secs

Question: 15 of 47

A 42-year-old lady presented with a two week history of noticing both her eyes were skewed towards the temporal side. She denied ocular pain and headaches. Her visual acuity was 6/6 on the Snellen chart in both eyes.

She was not able to adduct both eyes, but up and down gaze was fine. She had two previous episodes of optic neuritis in the right eye. The last episode happened four months ago.

Her walking was normal, and her deep tendon reflexes were present. She also had just recovered from gastroenteritis three weeks ago.

What is the most likely condition that the patient had presented with?

(Please select 1 option)

- Chronic progressive external ophthalmoplegia
- Internuclear ophthalmoplegia
- Miller Fisher syndrome
- Ocular myasthenia
- Parinaud's syndrome

Submit answer | Skip question | Tag Question | Remove question

side. She denied ocular pain and headaches. Her visual acuity was 6/6 on the Snellen chart in both eyes.

She was not able to adduct both eyes, but up and down gaze was fine. She had two previous episodes of optic neuritis in the right eye. The last episode happened four months ago.

Her walking was normal, and her deep tendon reflexes were present. She also had just recovered from gastroenteritis three weeks ago.

What is the most likely condition that the patient had presented with?

(Please select 1 option)

○	Chronic progressive external ophthalmoplegia
◉	Internuclear ophthalmoplegia ✓ Correct
○	Miller Fisher syndrome
○	Ocular myasthenia
○	Parinaud's syndrome

This is a case of walled eye bilateral internuclear ophthalmoplegia (WEBINO).

The history suggests a demyelinating process, and failure of ocular adduction in such cases should prompt the diagnosis of internuclear ophthalmoplegia.

Work Smart Session - MRCP Part 1

Time taken: 35 mins 7 secs

Question: 16 of 47

A 75-year-old man developed a gradual problem of not being able to look down over the last eight months. Then about two months ago, he was also not able to look up. He denied any diplopia, ocular pain or headaches.

There was no evidence of convergence retraction nystagmus, proptosis or ptosis.

What is the most likely diagnosis?

(Please select 1 option)

- Chronic progressive external ophthalmoplegia
- Ocular myasthenia
- Ocular myositis
- Parinaud's syndrome
- Thyroid eye disease

Question: 16 of 47

A 75-year-old man developed a gradual problem of not being able to look down over the last eight months. Then about two months ago, he was also not able to look up. He denied any diplopia, ocular pain or headaches.

There was no evidence of convergence retraction nystagmus, proptosis or ptosis.

What is the most likely diagnosis?

(Please select 1 option)

◉	Chronic progressive external ophthalmoplegia ✓ Correct
○	Ocular myasthenia
○	Ocular myositis
○	Parinaud's syndrome
○	Thyroid eye disease

The history itself suggests a chronic progressive limitation of eye movements without any diplopia, proptosis or ptosis. Therefore, the most likely diagnosis is chronic progressive external ophthalmoplegia.

Ocular myasthenia usually presents with diplopia and ptosis.

Parinaud's syndrome usually manifests as up gaze palsy with convergence retraction nystagmus.

Work Smart Session - MRCP Part 1

Time taken: 37 mins 6 secs

Question: 17 of 47

A 24-year-old lady with a body mass index (BMI) of 36 and on the combined oral contraceptive pill presented with a one month history of increasing vertex headaches, worse in the mornings and worse on coughing and sneezing. She also complained of blurry vision in both eyes.

Fundoscopy revealed bilateral extensive papilloedema with a lot of flame shaped haemorrhages around and on the optic discs.

Which one of the following is the best long term management of this patient?

(Please select 1 option)

○	Changing the combined oral contraceptive pill to an oestrogen based one
○	Commence on aspirin
○	Perform lumbar puncture
○	Reduce weight
○	Start oral acetazolamide

Submit answer | Skip question | Tag Question | Remove question

also complained of blurry vision in both eyes.

Fundoscopy revealed bilateral extensive papilloedema with a lot of flame shaped haemorrhages around and on the optic discs.

Which one of the following is the best long term management of this patient?

(Please select 1 option)

○	Changing the combined oral contraceptive pill to an oestrogen based one
○	Commence on aspirin
○	Perform lumbar puncture
◉	Reduce weight ✓ Correct
○	Start oral acetazolamide

This patient has idiopathic intracranial hypertension. The best long term management is weight reduction, which can improve her symptoms.

Changing the combined oral contraceptive pill to a more oestrogen based one can worsen the symptoms.

Lumbar puncture and acetazolamide can help improve the symptoms, but should not be considered as long term management.

Question: 18 of 47

A 26-year-old tall, thin, lady with a known cardiac valvulopathy, was reported to have skin laxity and folds on the back of the neck and her underarms.

Fundoscopy revealed bilateral angioid streaks with optic disc drusens.

What is the most likely diagnosis?

(Please select 1 option)

◉	Ehlers-Danlos syndrome ✗ Incorrect answer selected
○	Marfan's syndrome
○	Menkes syndrome
○	Osteogenesis imperfecta
○	Pseudoxanthoma elasticum ← This is the correct answer

Pseudoxanthoma elasticum with angioid streaks is also known as Grönblad-Strandberg syndrome.

Ehlers-Danlos and Marfan's syndrome are not associated with laxity and folds of skin on the back of the neck.

Menkes syndrome and osteogenesis imperfecta are not associated with angioid streaks.

Work Smart Session - MRCP Part 1

Time taken: 40 mins 22 secs

Question: 19 of 47

A 34-year-old man, who has just recovered from gastroenteritis following a recent trip to Turkey, suddenly developed progressive gait ataxia and restriction of eye movements in all directions of gaze.

There was no nystagmus.

What is the most likely diagnosis?

(Please select 1 option)

- Acute cerebellar degeneration
- Millard-Gubler syndrome
- Miller-Fisher syndrome
- Parinaud's syndrome
- Subacute combined degeneration of the spinal cord

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

What is the most likely diagnosis?

(Please select 1 option)

○	Acute cerebellar degeneration
○	Millard-Gubler syndrome
◉	Miller-Fisher syndrome ✓ Correct
○	Parinaud's syndrome
○	Subacute combined degeneration of the spinal cord

Miller-Fisher syndrome is a variant/spectrum of Guillain-Barré syndrome (GBS).

GBS is associated with *Campylobacter jejuni* infection, which can trigger this syndrome.

Miller-Fisher is classically described as a triad of

- External ophthalmoplegia
- Ataxia
- Areflexia

so the above history would be most in keeping with Miller-Fisher syndrome.

Next question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Medication includes clopidogrel, ramipril, atorvastatin, and metformin.

On examination his BP is 165/100 mmHg, his pulse is 76 and regular. Visual field examination reveals a right homonymous upper quadrantanopia.

Where is the most likely site for the underlying lesion?

(Please select 1 option)

○	Left occipital lobe
◉	Left temporal lobe ✓ Correct
○	Optic chiasm
○	Right optic nerve
○	Right temporal lobe

Temporal lobe lesions result in a bilateral homonymous hemianopia.

Occipital lobe lesions result in cortical blindness.

The most likely cause in this case is a thromboembolic event affecting the left temporal lobe. Given he has suffered multiple TIAs he should be considered for a work up including echocardiogram and carotid USS.

Anti-platelet management if tolerated should be with aspirin and dipyridamole as per the ESPS2 trial.

Work Smart Session - MRCP Part 1

Time taken: 3 mins 51 secs

Question: 2 of 47

A 29-year-old woman comes to the clinic because she is concerned that her left pupil is abnormally large. Her boyfriend noticed it and suggested she should see the doctor.

She has no past medical history of note, apart from an episode of shingles a few months earlier, and takes the oral contraceptive pill as her only medication. On further questioning she admits to unprotected sexual intercourse on two to three occasions over the past three to four years.

On examination her left pupil is clearly larger than the right. It hardly reacts to light at all, but does accommodate to near vision. You notice that re-dilatation is very slow however. Her BP is normal at 132/72 mmHg, and general physical examination is unremarkable.

How best can you confirm the diagnosis?

(Please select 1 option)

○	Chest x ray
○	Lumbar puncture
○	MRI brain
○	Reaction to weak miotic eye drops
◉	Syphilis serology

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 42 mins 2 secs

Question: 20 of 47

A 61-year-old emmetropic female nurse presented with a three day history of missing steps when walking down the stairs as she was seeing double of each of the steps. She reported no such problems when walking up the stairs.

She admitted to bumping her head moderately hard when trying to get out of her car four days ago. She denied any deterioration of her visual acuity.

No horizontal diplopia was elicited.

What is the most likely cause of her problems?

(Please select 1 option)

○	Right inferior oblique palsy
○	Right inferior rectus palsy
○	Right superior oblique palsy
○	Right superior rectus palsy
○	This patient needs glasses for distance

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

A 61-year-old emmetropic female nurse presented with a three day history of missing steps when walking down the stairs as she was seeing double of each of the steps. She reported no such problems when walking up the stairs.

She admitted to bumping her head moderately hard when trying to get out of her car four days ago. She denied any deterioration of her visual acuity.

No horizontal diplopia was elicited.

What is the most likely cause of her problems?

(Please select 1 option)

○	Right inferior oblique palsy
○	Right inferior rectus palsy
◉	Right superior oblique palsy ✓ Correct
○	Right superior rectus palsy
○	This patient needs glasses for distance

This patient essentially suffered from vertical diplopia following bumping her head moderately hard.

The fourth cranial nerve can be affected in such a situation resulting in superior oblique palsy.

Work Smart Session - MRCP Part 1

Time taken: 42 mins 9 secs

Question: 21 of 47

A 28-year-old Lebanese lady developed left branch retinal artery occlusion (BRAO) one week after an uneventful elective caesarean section. She also developed some mouth and vulval ulcers two weeks post-partum.

Visual acuity in the affected left eye was counting fingers.

Full blood picture, U&Es and coagulation screen were all within normal limits. CRP was 28. Anti-nuclear antibody, ANA titre was 1:20.

What is the most likely cause of her left BRAO?

(Please select 1 option)

○	Amniotic fluid embolus
○	Behçet's disease
○	Fat embolus
○	Reiter's syndrome
○	SLE

Submit answer | Skip question | Tag Question | Remove question

Full blood picture, U&Es and coagulation screen were all within normal limits. CRP was 28. Anti-nuclear antibody, ANA titre was 1:20.

What is the most likely cause of her left BRAO?

(Please select 1 option)

○	Amniotic fluid embolus
◉	Behçet's disease ✓ Correct
○	Fat embolus
○	Reiter's syndrome
○	SLE

Behçet's disease is an inflammatory condition of blood vessels of unknown aetiology. It is more common in people from the eastern Mediterranean and the Middle East.

The vasculitic process can affect many parts of the body, including the eye, which can lead to retinal artery occlusion among other things.

Mouth and genital ulcers with an inflammatory condition in a person from the Mediterranean region should make one think of Behçet's disease as the diagnosis.

Work Smart Session - MRCP Part 1

Time taken: 45 mins 1 secs

Question: 22 of 47

A 77-year-old male presents with sudden loss of vision in his right eye, associated with a relative afferent pupillary defect. He has poorly controlled systemic hypertension and raised cholesterol.

What is the most likely aetiology of his presentation?

(Please select 1 option)

○	Cataract
○	Chronic open angle glaucoma
○	Macular degeneration
○	Retinal vascular occlusion ← This is the correct answer
◉	Retinitis pigmentosa ✕ Incorrect answer selected

The history of acute loss of vision affecting one eye suggests an acute vascular occlusion, especially given the associated vascular risks.

The others cause a more chronic visual loss.

Work Smart Session - MRCP Part 1

Time taken: 45 mins 1 secs

Question: 23 of 47

A 24-year-old law student attends with visual loss affecting the right eye. She reports a constant headache for the last three months, and absence of menses for six months.

On examination her visual acuity in the right eye is 6/24, with slight constriction of the temporal field in that eye but she has no other neurological deficit. She is afebrile and haemodynamically stable.

What is the diagnosis?

(Please select 1 option)

○	Glaucoma
○	Migraine
○	Multiple sclerosis
○	Pituitary tumour
○	Pregnancy

Submit answer | Skip question | Tag Question | Remove question

she has no other neurological deficit. She is afebrile and haemodynamically stable.

What is the diagnosis?

(Please select 1 option)

○	Glaucoma
○	Migraine
○	Multiple sclerosis
◉	Pituitary tumour ✓ Correct
○	Pregnancy

This patient has a pituitary lesion; the history of headache and amenorrhoea suggests a prolactinoma or non-functioning tumour. This has been complicated by involvement of the visual pathway which has precipitated her visual loss.

She needs urgent assessment of her pituitary function and imaging of the pituitary gland by MRI scanning. One of the most important investigations to perform would be a serum prolactin.

The amenorrhoea would argue against this being retrobulbar neuritis associated with multiple sclerosis (MS), and similarly the peripheral visual field constriction would be unusual as a central scotoma and fluctuating visual loss would be more typical.

Work Smart Session - MRCP Part 1

Time taken: 46 mins 56 secs

Question: 24 of 47

A 60-year-old man presents with an acute red eye.

Of the following conditions which is the most likely cause?

(Please select 1 option)

- Closed angle glaucoma
- Optic neuritis
- Retinal vein occlusion
- Retinal detachment
- Vitreous haemorrhage

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

(Please select 1 option)

◉	Closed angle glaucoma ✓ Correct
○	Optic neuritis
○	Retinal vein occlusion
○	Retinal detachment
○	Vitreous haemorrhage

Of those listed the most likely to present with an acute red eye would be glaucoma.

Other causes of acute red eye include

- Anterior uveitis
- Corneal ulcers
- Conjunctivitis
- Scleritis
- Episcleritis
- Subconjunctival haemorrhage.

Optic neuritis presents with a particular type of central visual loss - a central scotoma.

Retinal vein occlusion, retinal detachment and vitreous haemorrhage would present as visual loss or disturbance.

A 26-year-old man presented with a 24 hour history of blurred vision in the left eye and mild left frontal headache. He had a ten year history of diabetes mellitus.

Examination of the left eye revealed a central scotoma.

What is the most likely diagnosis?

(Please select 1 option)

○	Central retinal artery occlusion
○	Diabetic retinopathy
○	Migraine
◉	Optic neuritis ✓ Correct
○	Pituitary tumour

Occlusion of the central retinal artery or one of its branches which supplies the macular region will result in almost immediate diminution or loss of visual acuity in the involved eye and is usually without pain.

In a young diabetic the aetiology is usually an embolus of the central retinal artery or one of its branches. However there is pain associated with this visual loss, namely headache.

Diabetes is a cause of optic neuritis which is usually associated with headache.

Retinopathy, per se, would not lead to an acute central scotoma unless there was acute bleeding from neovascularisation.

Work Smart Session - MRCP Part 1

Time taken: 51 mins 20 secs

Question: 26 of 47

A 35-year-old woman is referred with right eye pain that has deteriorated over the last week.

On examination she had a mild ptosis of the right eye and was aware of diplopia with vertical image separation on looking upwards. She also had weakness of elevation of the right eye.

What is the most likely diagnosis?

(Please select 1 option)

- Cavernous sinus thrombosis
- Graves' ophthalmopathy
- Myasthenia gravis
- Posterior communicating artery aneurysm
- Sphenoid sinusitis

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

On examination she had a mild ptosis of the right eye and was aware of diplopia with vertical image separation on looking upwards. She also had weakness of elevation of the right eye.

What is the most likely diagnosis?

(Please select 1 option)

○	Cavernous sinus thrombosis
○	Graves' ophthalmopathy
○	Myasthenia gravis
◉	Posterior communicating artery aneurysm ✓ Correct
○	Sphenoid sinusitis

The signs are consistent with a partial third nerve palsy associated with periorbital pain.

In a young person a posterior communicating artery aneurysm needs to be excluded.

With cavernous sinus thrombosis one should expect some other signs such as periorbital swelling, proptosis, and conjuctival injection.

With Graves' eye disease one should expect proptosis and lid retraction.

Myasthenia gravis does not present with pain.

Work Smart Session - MRCP Part 1

Time taken: 54 mins 35 secs

Question: 27 of 47

A 18-year-old male presents with blurring of vision in his right eye.
Examination reveals visual acuity in the right eye of 6/18 and in the left eye 6/6.

Visual fields to confrontation reveal a right temporal visual field defect and partial loss of superior part of the temporal field of the left eye.

Where is the most likely position of the lesion responsible for this defect?

(Please select 1 option)

○	Occipital lobe
○	Optic chiasm
○	Optic nerve
○	Optic tract
○	Temporal lobe

Submit answer | Skip question | Tag Question | Remove question

A 18-year-old male presents with blurring of vision in his right eye.
Examination reveals visual acuity in the right eye of 6/18 and in the left eye 6/6.

Visual fields to confrontation reveal a right temporal visual field defect and partial loss of superior part of the temporal field of the left eye.

Where is the most likely position of the lesion responsible for this defect?

(Please select 1 option)

○	Occipital lobe
◉	Optic chiasm ✓ Correct
○	Optic nerve
○	Optic tract
○	Temporal lobe

The most likely localisation of the lesion is around the optic chiasm spreading up the right optic nerve. The signs indicate a bitemporal visual field defect with involvement of the right optic nerve (decreased visual acuity).

Occipital lobe lesion causes a congruous homonymous hemianopia whereas an optic tract lesion causes an incongruous homonymous hemianopia. Temporal lobe lesion causes an upper homonymous quantranopia.

Visual fields See also references.

Work Smart Session - MRCP Part 1

Time taken: 57 mins 3 secs

Question: 28 of 47

A 30-year-old man complains of fairly rapid worsening of his central vision. His acuity is normal on pinhole testing.

Which of the following would not account for his symptoms?

(Please select 1 option)

○	Diabetes mellitus
○	Eye drops
○	Eyelid swelling
○	Lens subluxation
○	Open angle glaucoma

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

○	Diabetes mellitus
○	Eye drops
○	Eyelid swelling
◉	Lens subluxation ✕ Incorrect answer selected
○	Open angle glaucoma ← This is the correct answer

The defect in this patient's vision is corrected by viewing through a pinhole, which means that the problem is refractive and must therefore be localised to the cornea or the lens.

Causes of rapid changes in refractive error include:

- Senile cataract (increasingly myopic)
- Diabetes mellitus (high glucose raises refractive index of lens, hence myopic)
- Keratoconus (conical cornea, may occur rapidly in adolescence or early adulthood and causes myopia and astigmatism)
- Subluxation of the lens
- Eye drops (miotics produce myopia, mydriatics lead to hypermetropia) and
- Eyelid swelling.

Open angle glaucoma is associated with damage to the ganglion cells of the retina and therefore any visual deficit that is produced by it will not correct with a pinhole.

Work Smart Session - MRCP Part 1

Time taken: 59 mins 18 secs

Question: 29 of 47

A 70-year-old female who has a history of chronic anxiety presents with a three day history of severe left temporal headache radiating from the eye to the scalp. She had also experienced discomfort during eating.

Which one of the following drugs should be given to this patient while awaiting the results of diagnostic tests?

(Please select 1 option)

- Acyclovir
- Carbamazepine
- Diclofenac
- Prednisolone
- Sumatriptan

Submit answer | Skip question | Tag Question | Remove question

Question: 29 of 47

A 70-year-old female who has a history of chronic anxiety presents with a three day history of severe left temporal headache radiating from the eye to the scalp. She had also experienced discomfort during eating.

Which one of the following drugs should be given to this patient while awaiting the results of diagnostic tests?

(Please select 1 option)

○	Acyclovir
○	Carbamazepine
○	Diclofenac
◉	Prednisolone ✓ Correct
○	Sumatriptan

The history suggests temporal arteritis irrespective of the history of anxiety and in view of the sight-threatening nature of the disease, the patient should be commenced on steroids.

Although the differential diagnosis is also trigeminal neuralgia, steroids should be used here whilst awaiting diagnostic investigations as temporal arteritis may be sight-threatening if left untreated.

Next question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

physical examination is unremarkable.

How best can you confirm the diagnosis?

(Please select 1 option)

○	Chest x ray
○	Lumbar puncture
○	MRI brain
○	Reaction to weak miotic eye drops ← This is the correct answer
◉	Syphilis serology ✕ Incorrect answer selected

This history is typical of an Adie's tonic pupil, which is characteristically seen in young women, and may occur after an episode of zoster infection.

At the beginning of the condition the pupil is large, but over time becomes small and poorly reactive. Slit lamp examination may reveal small worm like contractions of the iris, but the usual diagnostic test is to use weak pilocarpine eye drops, which induce vigorous pupil contraction on the affected side, but only weak contraction of the pupil on the unaffected side.

In adults it tends to be a benign condition and is simply observed, however infants are usually referred because of an association with familial dystonias.

Question: 30 of 47

A 35-year-old woman with type 1 diabetes mellitus presents for annual assessment.

Which one of the following features on fundoscopy would require urgent referral to an ophthalmologist?

(Please select 1 option)

○	Asteroid bodies
○	Hard exudates in the macular region ← This is the correct answer
○	Intraretinal microvascular abnormalities
○	Scattered microaneurysms
◉	Soft exudates ✕ Incorrect answer selected

Scattered microaneurysms signify background DRn.

Intraretinal microvascular abnormalities (IRMAs) and soft exudates signify pre-proliferative retinopathy.

According to the NIeH, urgent referral to an ophthalmologist (seen within one week) is required if there is proliferative retinopathy or there is evidence of clinically significant macular oedema (hard exudates at the fovea).

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 51 secs

Question: 31 of 47

A 60-year-old male who was previously fit and well presented with a six week history of blurring of vision.

His investigation revealed a fasting plasma glucose of 12.9 mmol/L (3.0 - 6.0).

What is the most likely cause of his blurred vision?

(Please select 1 option)

○	Cataract
○	Maculopathy
○	Osmotic changes in the lens
○	Proliferative diabetic retinopathy
○	Retinal vein thrombosis

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 2 mins 43 secs

Question: 31 of 47

A 60-year-old male who was previously fit and well presented with a six week history of blurring of vision.

His investigation revealed a fasting plasma glucose of 12.9 mmol/L (3.0 - 6.0).

What is the most likely cause of his blurred vision?

(Please select 1 option)

○	Cataract
○	Maculopathy
◉	Osmotic changes in the lens ✓ Correct
○	Proliferative diabetic retinopathy
○	Retinal vein thrombosis

Without being given too much here, this patient is a newly diagnosed diabetic as we are told he was previously fit and well.

Therefore the most probable explanation for his blurred vision is osmotic change.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 2 mins 43 secs

Question: 32 of 47

A 17-year-old male with learning difficulties is brought for review by his worried parents after he described acute blurring of vision in his right eye.

Examination reveals ectopia lentis.

What is the most likely diagnosis?

(Please select 1 option)

○	Ehlers-Danlos syndrome
◉	Homocystinuria
○	Maple syrup urine disease
○	Marfan's syndrome
○	Metachromatic leukodystrophy

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Shop

◉	Homocystinuria ✓ Correct
○	Maple syrup urine disease
○	Marfan's syndrome
○	Metachromatic leukodystrophy

- Ectopia lentis/ subluxation of the lens is associated with:
-
- Ehlers-Danlos syndrome
- Marfan's syndrome
- Weil-Marchesani syndrome (short stature, skeletal abnormalities and ectopia lentis)
- Refsum's disease.
-
- In this case homocystinuria is likely due to the associated mental retardation.
-
- Patients typically have fair skin with coarse hair, osteoporosis, mental retardation (nearly 50%), seizure disorder, marfanoid habitus, and and increased thromboembolic risk.
-
- Metachromatic leukodystrophy is a lysosomal storage disorder characterised by lipid (sulfatide) accumulation in the central nervous system and associated with psychomotor retardation in infants with optic atrophy and blindness.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 4 mins 20 secs

Question: 33 of 47

A 23-year-old man presents with visual loss in his right eye and this is diagnosed as optic neuritis.

Which one of the following statements would be seen in an afferent pupillary defect?

(Please select 1 option)

- Accommodation response is unaffected
- Hypersensitive response to pilocarpine in the affected eye
- Irregular pupil of the affected eye
- Pupil of affected eye larger than the unaffected eye
- Pupil of affected eye smaller than the unaffected eye

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 5 mins 56 secs

Question: 33 of 47

A 23-year-old man presents with visual loss in his right eye and this is diagnosed as optic neuritis.

Which one of the following statements would be seen in an afferent pupillary defect?

(Please select 1 option)

○	Accommodation response is unaffected ← This is the correct answer
◉	Hypersensitive response to pilocarpine in the affected eye ✕ Incorrect answer selected
○	Irregular pupil of the affected eye
○	Pupil of affected eye larger than the unaffected eye
○	Pupil of affected eye smaller than the unaffected eye

Optic neuropathy **does not** cause any abnormalities of the shape or size of the pupil.

However the light reaction is diminished.

Accommodation is normal.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 6 mins 59 secs

Question: 34 of 47

A 72-year-old male presented with a quadrantic hemianopia.

Which of the following conditions is most likely to cause such a presentation?

(Please select 1 option)

○	A lesion of the occipital cortex ← This is the correct answer
◉	A lesion of the optic chiasma ✕ Incorrect answer selected
○	Bilateral diabetic retinopathy
○	Chloroquine poisoning
○	Tobacco amblyopia

A lesion of the optic chiasm would cause a bitemporal hemianopia.

Diabetic retinopathy may cause an 'apparent quadrantic hemianopia' because the distribution of the retinal changes may just correspond to quadrantic hemianopia - but this is not the most likely.

Tobacco amblyopia causes symmetric central or centrocaecal scotomas.

Chloroquine poisoning causes symmetric bilateral scotomas.

Regarding retinoblastoma which of the following statements is correct?

(Please select 1 option)

◉	Bilateral involvement is found in 70% of cases. ✕ Incorrect answer selected
○	The predisposition may be inherited as an autosomal recessive condition.
○	There is an increased risk of autoimmune disease.
○	They have often metastasised by the time of diagnosis.
○	They usually present with leukocoria. ← This is the correct answer

The incidence is 1 in 16,000 live births.

Genetic predisposition occurs in 20% of patients with unilateral disease, and 30% of patients with bilateral disease.

The gene has been localised to 13q and the inherited form is associated with an increased risk of malignancy such as osteosarcoma and pineal tumours. It may be inherited as autosomal dominant.

The commonest presentation is leukocoria (yellowish white pupil reflex), and there may be diminished or absent vision or strabismus.

Late symptoms are pupil irregularity, hyphema, pain, proptosis, and signs of raised intracranial pressure.

The tumours have rarely metastasised before they are detected.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 8 mins 4 secs

Question: 36 of 47

Which of the following concerning diabetic retinopathy is correct?

(Please select 1 option)

○	Improved glycaemic control is more effective than hypertensive control in reducing progression of disease.
○	Is unusual in patients with type 2 diabetes
◉	Normal visual acuity is seen in proliferative retinopathy. ✓ Correct
○	Progression may be reduced with statin therapy
○	Soft exudates are a feature of background retinopathy.

Diabetic retinopathy occurs in both type 1 and 2 DM and may be a presenting feature in type 2 as the condition may have existed for many years prior to diagnosis.

Progression may be slowed with improved glycaemic and hypertensive control but the latter has been shown to be more effective at reducing progression (UKPDS).

There are no data at present to suggest that statin therapy reduces disease progression.

Soft exudates are a feature of pre-proliferative Rn and despite quite marked new vessel disease the visual acuity may be normal.

Next question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 8 mins 4 secs

Question: 37 of 47

A 72-year-old male presents with diplopia.

Which one of the following features would suggest a third nerve palsy?

(Please select 1 option)

○	Enophthalmos
○	Constricted pupil
○	Convergent strabismus
○	Increased lacrimation
○	Unreactive pupil to light

Submit answer | Skip question | Tag Question | Remove question

Question: 37 of 47

A 72-year-old male presents with diplopia.

Which one of the following features would suggest a third nerve palsy?

(Please select 1 option)

○	Enophthalmos
○	Constricted pupil
○	Convergent strabismus
○	Increased lacrimation
◉	Unreactive pupil to light ✓ Correct

In a third nerve palsy, there is typically ptosis with a dilated unreactive pupil and the eyeball is displaced downwards and outwards.

Enophthalmos is seen in Horner's syndrome. There would be a dilated not constricted pupil and a divergent squint, with the affected eye deviated 'down and out'.

Increased lacrimation may be seen in VIIth palsy.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 9 mins 8 secs

Question: 38 of 47

Which one of the following diagnoses is associated with acute iritis?

(Please select 1 option)

- Keratoconus
- Lyme disease
- Osteogenesis imperfecta
- Psoriatic arthropathy
- Refsum's disease

Submit answer | Skip question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which one of the following diagnoses is associated with acute iritis?

(Please select 1 option)

○	Keratoconus
◉	Lyme disease ✕ Incorrect answer selected
○	Osteogenesis imperfecta
○	Psoriatic arthropathy ← This is the correct answer
○	Refsum's disease

Iritis is associated with conditions such as Reiter's, Behcet's, psoriatic arthropathy (about 20%) and inflammatory bowel disease.

A chronic iritis is rarely described in association with Lyme disease.

Osteogenesis imperfecta is associated with blue sclera.

Keratoconus, meaning "cone shaped," describes a condition in which the cornea (the clear front window of the eye) becomes thin and protrudes. This abnormal shape can cause serious distortion of visual images. It is not associated with iritis.

Refsum's disease is associated with retinitis pigmentosa.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 9 mins 58 secs

Question: 39 of 47

A 16-year-old girl presented with a three week history of headache and horizontal diplopia on far right lateral gaze. On two separate occasions she noted dimmed vision whilst bending forwards. Over the last year she had gained 12 kilograms in weight.

On examination, her weight was 95 kg, and height 162 cms.

Neurological examination revealed bilateral papilloedema and a partial right sixth cranial nerve palsy.

What is the most likely diagnosis?

(Please select 1 option)

○	Benign intracranial hypertension (BIH).
○	Multiple sclerosis.
○	Pituitary tumour
○	Superior sagittal vein thrombosis.
○	Thyroid eye disease.

Submit answer | Skip question | Tag Question | Remove question

- Shop

What is the most likely diagnosis?

(Please select 1 option)

◉	Benign intracranial hypertension (BIH). ✓ Correct
○	Multiple sclerosis.
○	Pituitary tumour
○	Superior sagittal vein thrombosis.
○	Thyroid eye disease.

This patient is markedly obese with a BMI of 36 and the history suggestive of BIH.

Vision may be affected with enlargement of the blind spot and the visual obscuration with movements that provoke a rise in intracranial pressure (ICP) (for example, bending) is typical of BIH.

Dysthyroid eye disease would not present like this and is more commonly associated with hyperthyroidism.

The papilloedema would argue against multiple sclerosis (MS).

A bitemporal hemianopia or a visual field defect would be expected with a pituitary tumour.

Venous sinus thrombosis is a possibility but would be expected to produce deteriorating symptoms.

Next question | Tag Question | Remove question

© 2011 BMJ Publishing Group Ltd . All rights reserved . Terms and conditions . Privacy policy . A A A

Which of the following anti-tuberculous agents is most likely to have been responsible?

(Please select 1 option)

◉	Ethambutol ✓ Correct
○	Isoniazid
○	Pyrazinamide
○	Rifampicin
○	Streptomycin

The answer is ethambutol, which is associated with

- Retrobulbar neuritis
- Generalised cutaneous reactions
- Hepatitis
- Peripheral neuropathy.

The retrobulbar neuritis seen with ethambutol may be unilateral or bilateral; as such unilateral symptoms do not preclude the diagnosis.

- Isoniazid is associated with peripheral neuropathy, skin rash and hepatitis
- Pyrazinamide with arthralgia and hepatitis and
- Streptomycin with vestibular and auditory nerve damage.

Work Smart Session - MRCP Part 1

Time taken: 6 mins 45 secs

Question: 4 of 47

A 24-year-old lady presented with anisocoria, with the right pupil larger than the left, both in a brightly lit room and in a dim lit room. Her mother noticed this only five days ago.

The anisocoria was less marked in the dim lit room. Deep tendon reflexes were present and brisk throughout.

She occasionally noted horizontal diplopia with a right sided headache. There was no ptosis. Visual acuity was 6/6 on the Snellen chart in both eyes.

Which one of the following statements is most accurate?

(Please select 1 option)

○	The diagnosis is Holmes-Adie's syndrome
○	The diagnosis of a brain tumour needs to be excluded urgently
○	The diagnosis of a posterior communicating artery aneurysm needs to be excluded urgently
○	The pathological (diseased) pupil is actually the left pupil, diagnosis being Argyll Robertson pupil
○	When doing a swinging light test of the pupils, a right relative afferent papillary defect is to be expected

A patient presents with deteriorating vision.

On examination, fundoscopy reveals retinitis pigmentosa.

Which of the following conditions would be unlikely to be responsible for this presentation?

(Please select 1 option)

○	Abetalipoproteinaemia
○	Friedreich's ataxia ← This is the correct answer
○	Kearns-Sayre syndrome
◉	Laurence-Moon-Biedl syndrome ✕ Incorrect answer selected
○	Refsum's disease

Causes of pigmentary retinopathy include Usher's syndrome and mitochondrial myopathy.

Abetalipoproteinaemia is autosomal recessive and is associated with:

- Hypocholesterolaemia syndrome resembling Friedreich's ataxia
- Abnormally shaped red blood cells (RBC) (acanthocytes)
- Steatorrhoea and
- Fatty liver.

Friedreich's is associated with optic atrophy.

Question: 41 of 47

A 22-year-old female presents with a month history of episodic, brief visual loss affecting the right eye.

Over the last one year she had gained a considerable amount of weight. Examination reveals a BMI of 35, with bilateral optic disc swelling, worse on the right and small retinal haemorrhages on the right.

What is the most likely diagnosis?

(Please select 1 option)

◉	Benign intracranial hypertension (BIH) ✓ Correct
○	Craniopharyngioma
○	Graves' ophthalmopathy
○	Optic neuritis
○	Sagittal sinus thrombosis

This is a classic description of BIH.

Drugs such as tetracyclines, the oral contraceptive or pregnancy may be contributory.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 13 mins 37 secs

Question: 42 of 47

A 30-year-old female presents to the eye clinic with an acute history of pain and blurring in the right eye.

Examination reveals a visual acuity of 6/36 in the right eye but 6/6 in the left eye, a central scotoma in the right eye, with a right swollen optic disc.

What is the most likely diagnosis?

(Please select 1 option)

- Cavernous sinus thrombosis
- Compression of the optic nerve
- Glaucoma
- Optic neuritis
- Retinal vein occlusion

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 14 mins 49 secs

Question: 42 of 47

A 30-year-old female presents to the eye clinic with an acute history of pain and blurring in the right eye.

Examination reveals a visual acuity of 6/36 in the right eye but 6/6 in the left eye, a central scotoma in the right eye, with a right swollen optic disc.

What is the most likely diagnosis?

(Please select 1 option)

○	Cavernous sinus thrombosis
○	Compression of the optic nerve
○	Glaucoma
◉	Optic neuritis ✓ Correct
○	Retinal vein occlusion

The acute presentation with central scotoma, reduced visual acuity and a swollen optic disc in a young female suggests a diagnosis of multiple sclerosis with a retrobulbar neuritis.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 14 mins 49 secs

Question: 43 of 47

A 50-year-old man with a history of diabetis mellitus and hypertension attends an ophthalmic clinic for regular assessment.

On fundoscopy he is diagnosed to have preproliferative diabetic retinopathy.

Which of the following is characteristic of preproliferative diabetic retinopathy?

(Please select 1 option)

○	Hard exudates
○	Macular oedema
○	Microaneurysms
○	New vessels at the disc
○	Venous beading

Submit answer | Skip question | Remove question

A 50-year-old man with a history of diabetis mellitus and hypertension attends an ophthalmic clinic for regular assessment.

On fundoscopy he is diagnosed to have preproliferative diabetic retinopathy.

Which of the following is characteristic of preproliferative diabetic retinopathy?

(Please select 1 option)

○	Hard exudates
○	Macular oedema
○	Microaneurysms
○	New vessels at the disc
◉	Venous beading ✓ Correct

Microaneurysms and hard exudates are features of background diabetic retinopathy.

Macular oedema is associated with microaneurysms and hard exudates and is due to fluid leakage but is not necessarily a feature pre-proliferative or proliferative retinopathy although it may still require laser photocoagulation.

Venous beading, loops and soft exudates (cotton wool spots) are characteristic of the ischaemia associated with preproliferative diabetic retinopathy.

New vessels suggest proliferative retinopathy.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 15 mins 38 secs

Question: 44 of 47

Which of the following may be associated with optic atrophy (OA)?

(Please select 1 option)

○	Anti-acetylcholinesterase antibodies
○	Intense iron deposition on liver biopsy
○	Low plasma caeruloplasmin
○	Red ragged fibres on muscle biopsy
○	XXY karyotype

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 16 mins 57 secs

Question: 44 of 47

Which of the following may be associated with optic atrophy (OA)?

(Please select 1 option)

○	Anti-acetylcholinesterase antibodies
○	Intense iron deposition on liver biopsy
○	Low plasma caeruloplasmin
◉	Red ragged fibres on muscle biopsy ✓ Correct
○	XXY karyotype

Red ragged fibres found in mitochondrial myopathy are found in Kearns-Sayre syndrome; mitochondrial myopathy, lactic acidosis and stroke-like episodes (MELAS); and Leber's optic atrophy.

Wilson's disease is associated with KF rings; and myotonic dystrophy rather than myasthenia gravis is associated with OA.

OA is not associated with Klinefelter's disease.

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 16 mins 57 secs

Question: 45 of 47

Causes of dilated pupils include:

(Please select 1 option)

- Argyll Robertson pupil
- Ethylene glycol poisoning
- Myotonic dystrophy
- Organophosphate poisoning
- Pontine haemorrhage

Submit answer | Skip question | Tag Question | Remove question

○	Argyll Robertson pupil
◉	Ethylene glycol poisoning ✓ Correct
○	Myotonic dystrophy
○	Organophosphate poisoning
○	Pontine haemorrhage

Causes of dilated pupils include:

- Holmes-Adie (myotonic) pupil

- third nerve palsy

- drugs and poisons (atropine, cobalt [CO], ethylene glycol).

Causes of small pupils include:

- Horner's syndrome

- old age

- pontine haemorrhage

- Argyll Robertson pupil

- drugs and poisons (opiates, organophosphates).

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 17 mins 43 secs

Question: 46 of 47

Causes of a small pupil include:

(Please select 1 option)

- Carbon monoxide poisoning
- Ethylene glycol poisoning
- Holmes-Adie pupil
- Pontine haemorrhage
- Third nerve palsy

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 18 mins 4 secs

Question: 47 of 47

Which of the following conditions is associated with a pathognomonic retinal change?

(Please select 1 option)

○	Infective endocarditis
○	Polycythaemia rubra vera
○	Sickle cell anaemia
○	Toxoplasmosis
◉	Wilson's disease

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 1 hrs 19 mins 51 secs

Question: 47 of 47

Which of the following conditions is associated with a pathognomonic retinal change?

(Please select 1 option)

○	Infective endocarditis
○	Polycythaemia rubra vera
○	Sickle cell anaemia ← This is the correct answer
○	Toxoplasmosis
◉	Wilson's disease ✕ Incorrect answer selected

Sickle cell disease (SCD) is associated with the 'black sunburst' - a chorioretinal scar, which is one of the commoner retinal manifestations of SCD and pathognomonic.

Roth spots, seen in infective endocarditis, are also seen in leukaemia.

Choroidoretinitis in toxoplasmosis may also be seen with other disorders.

The Kayser-Fleischer (KF) rings of Wilson's disease are found on the iris.

A 24-year-old lady presented with anisocoria, with the right pupil larger than the left, both in a brightly lit room and in a dim lit room. Her mother noticed this only five days ago.

The anisocoria was less marked in the dim lit room. Deep tendon reflexes were present and brisk throughout.

She occasionally noted horizontal diplopia with a right sided headache. There was no ptosis. Visual acuity was 6/6 on the Snellen chart in both eyes.

Which one of the following statements is most accurate?

(Please select 1 option)

○	The diagnosis is Holmes-Adie's syndrome
○	The diagnosis of a brain tumour needs to be excluded urgently
○	The diagnosis of a posterior communicating artery aneurysm needs to be excluded urgently ← This is the correct answer
◉	The pathological (diseased) pupil is actually the left pupil, diagnosis being Argyll Robertson pupil ✕ Incorrect answer selected
○	When doing a swinging light test of the pupils, a right relative afferent papillary defect is to be expected

The history of anisocoria, with headaches and diplopia should ring alarm bells, in that a life-threatening posterior communicating artery aneurysm/berry aneurysm needs to be excluded urgently.

Anisocoria being an efferent problem will not give a relative afferent papillary defect.

Work Smart Session - MRCP Part 1

Time taken: 10 mins 18 secs

Question: 5 of 47

An 18-year-old man was found to have multiple small pigmented lesions in the peripheral retina of both eyes.

These lesions resembled bear tracks. However, his visual acuity was 6/6 on the Snellen chart in both eyes. His father also had similar lesions.

Which one of the following would be the best next step in managing this man's condition?

(Please select 1 option)

- Referral to cardiology
- Referral to endocrinology
- Referral to gastroenterology
- Referral to infectious disease specialist
- Referral to ophthalmology

Question: 5 of 47

An 18-year-old man was found to have multiple small pigmented lesions in the peripheral retina of both eyes.

These lesions resembled bear tracks. However, his visual acuity was 6/6 on the Snellen chart in both eyes. His father also had similar lesions.

Which one of the following would be the best next step in managing this man's condition?

(Please select 1 option)

○	Referral to cardiology
○	Referral to endocrinology
○	Referral to gastroenterology ← This is the correct answer
○	Referral to infectious disease specialist
◉	Referral to ophthalmology ✕ Incorrect answer selected

This description of the lesion is that of congenital hypertrophy of retinal pigment epithelium (CHRPE), which is associated with autosomal dominantly inherited familial adenomatous polyposis (FAP).

A referral to gastroenterology is the best next step.

Work Smart Session - MRCP Part 1

Time taken: 13 mins 42 secs

Question: 6 of 47

A 47-year-old man, otherwise fit and healthy, complained of a one week history of not being able to see objects placed at the centre of his visual fields, even with both eyes opened.

An objective visual fields test revealed an incongruous binasal hemianopia.

What is the most likely diagnosis?

(Please select 1 option)

○	Carotid-cavernous sinus fistula
◉	Craniopharyngioma
○	External carotid artery dissection
○	Internal carotid artery displacement
○	Pituitary tumour

Submit answer | Skip question | Tag Question | Remove question

Work Smart Session - MRCP Part 1

Time taken: 16 mins 12 secs

Question: 6 of 47

A 47-year-old man, otherwise fit and healthy, complained of a one week history of not being able to see objects placed at the centre of his visual fields, even with both eyes opened.

An objective visual fields test revealed an incongruous binasal hemianopia.

What is the most likely diagnosis?

(Please select 1 option)

○	Carotid-cavernous sinus fistula
◉	Craniopharyngioma ✕ Incorrect answer selected
○	External carotid artery dissection
○	Internal carotid artery displacement ← This is the correct answer
○	Pituitary tumour

Bilateral internal carotid artery displacement can cause binasal incongruous hemianopia if the optic nerves are compressed.

Work Smart Session - MRCP Part 1

Time taken: 16 mins 12 secs

Question: 7 of 47

A 45-year-old lady with rheumatoid arthritis attended a routine appointment at the rheumatology clinic, and was complaining of a two day history of right red eye with dull pain.

She denied any photophobia and there was no ocular discharge noted.

What is the most likely diagnosis?

(Please select 1 option)

○	Acute angle closure glaucoma
○	Conjunctivitis
○	Inflammation caused by corneal melt
◉	Scleritis
○	Scleromalacia perforans

Submit answer | Skip question | Tag Question | Remove question

Question: 7 of 47

A 45-year-old lady with rheumatoid arthritis attended a routine appointment at the rheumatology clinic, and was complaining of a two day history of right red eye with dull pain.

She denied any photophobia and there was no ocular discharge noted.

What is the most likely diagnosis?

(Please select 1 option)

○	Acute angle closure glaucoma
○	Conjunctivitis
○	Inflammation caused by corneal melt
◉	Scleritis ✓ Correct
○	Scleromalacia perforans

Rheumatoid arthritis is associated with both scleritis and episcleritis. Scleritis may cause severe pain and results in diffuse or nodular injection. Episcleritis results in ocular irritation with nodules.

In the absence of photophobia and discharge, scleritis would be the best answer.

Work Smart Session - MRCP Part 1

Time taken: 17 mins 14 secs

Question: 8 of 47

A 25-year-old man presented with night blindness and gradual deterioration of his peripheral visual fields bilaterally.

Ocular examination revealed bony spiculed lesions in the peripheral retina of both eyes with attenuated retinal blood vessels.

His only other past medical history is that of a first degree heart block.

Which one of the following statements is most correct?

(Please select 1 option)

○	There is a one in two chance of him passing this disease on to his offspring
○	There is a one in four chance of him passing this disease on to his offspring
○	There is a one in 10 chance of him passing this disease on to his offspring
○	There is a 100% chance of him passing this disease on to his offspring
○	There is no chance of him passing this disease on to his offspring

Submit answer | Skip question | Tag Question | Remove question

vessels.

His only other past medical history is that of a first degree heart block.

Which one of the following statements is most correct?

(Please select 1 option)

◉	There is a one in two chance of him passing this disease on to his offspring ✗ Incorrect answer selected
○	There is a one in four chance of him passing this disease on to his offspring
○	There is a one in 10 chance of him passing this disease on to his offspring
○	There is a 100% chance of him passing this disease on to his offspring
○	There is no chance of him passing this disease on to his offspring ← This is the correct answer

The diagnosis is Kearns-Sayre syndrome.

This is a mitochondrial inherited disease, and as such is only passed on by mothers to offspring.

It is a slowly progressive neuromuscular disorder associated with progressive external ophthalmoplegia and heart conduction defect.

Ocular manifestations include ptosis and peripheral retinal bony spiculed appearances.

Work Smart Session - MRCP Part 1

Time taken: 19 mins 51 secs

Question: 9 of 47

A 75-year-old man, known to have ischaemic heart disease, with a previous history of alcohol abuse, presented with a one week history of deterioration of central vision in the right eye.

He denied any ocular pain or headache. An objective visual fields test was done and he was found to have a right central scotoma.

What is the most likely diagnosis?

(Please select 1 option)

○	Alcohol toxic amblyopia
○	Macular degeneration
○	Ocular ischaemic syndrome
○	Vitamin A deficiency
○	Vitamin B_{12} deficiency

A 75-year-old man, known to have ischaemic heart disease, with a previous history of alcohol abuse, presented with a one week history of deterioration of central vision in the right eye.

He denied any ocular pain or headache. An objective visual fields test was done and he was found to have a right central scotoma.

What is the most likely diagnosis?

(Please select 1 option)

○	Alcohol toxic amblyopia
○	Macular degeneration ← This is the correct answer
○	Ocular ischaemic syndrome
○	Vitamin A deficiency
◉	Vitamin B_{12} deficiency ✕ Incorrect answer selected

This history is most in keeping with macular degeneration.

The relatively short history is more suggestive of wet age-related macular degeneration, which is actually a systemic problem, of which ischaemic heart disease is a risk factor.

Toxic amblyopia will more often give a centro-caecal scotoma.

Central scotoma here indicates that only the macula region is involved.
